Fig. 2 Genome organization and expression of tobacco necrosis virus A. G-RNA, genomic RNA; sg1 RNA, sub-genomic RNA 1; sg2 RNA, sub-genomic RNA 2; RT, readthrough; CP, coat protein. Molecular weights of the ORF-encoded proteins (p) are indicated.

BBSV), partially overlapping the C-terminus of ORF1-RT and the N-terminal region of ORF2. The genome is very compact, having noncoding regions of limited size (Fig. 2). To compensate for the lack of a 5' cap or a 3' poly(A), RNA *cis*-elements are required for cap-independent translation of the virus genome. A cap-independent translational enhancer (CITE) has been identified in the 3'-end untranslated region (UTR) of all necro-like viruses, belonging to the Barley yellow dwarf virus (BYDV) like-element (BTE) class of CITEs. The BTE has a helical cloverleaf-like structure and contains a highly conserved nucleotide stretch able to form a stem-loop structure, and binds the eukaryotic translation initiation factor 4F (eIF4F) complex.

Genomic RNA acts as messenger for the translation of a protein of 22–24 kDa from ORF1. By translational readthrough of the UAG termination codon of ORF1, a protein of 82–83 kDa is synthesized (Fig. 2), which contains, in the readthrough portion, the conserved GDD motif of RNA-dependent RNA polymerases (RdRp). This protein, together with the expression product of ORF1, is indispensable for virus replication. RNA elements have been identified in TNV-D genome, which are able to modulate the readthrough efficiency.

Genes downstream ORF1-RT are expressed *via* the synthesis of two sub-genomic RNAs, 1.4–1.6 nt and 1.1–1.3 nt in size (Fig. 2). The larger sub-genomic RNA is responsible for the expression of ORFs 2 and 3, whereas the smaller sub-genomic RNA

constitutes the translational template for the expression of CP. ORFs 2 and 3 are two small, centrally located ORFs which, depending on the viral species, encode proteins of 7–8 and 6–7 kDa, respectively. Both of these proteins are involved in cell-to-cell transport but are dispensable for viral replication. LWSV ORF2 differs in size from that of other sequenced necro-like viruses, for it codes for a protein of 11 kDa. The additional central ORFs of TNV-D^H and BBSV code for a 7 kDa and a 5 kDa protein, respectively, which, like the products of ORFs 2 and 3, are necessary for cell-to-cell movement. A possible transmembrane motif has been predicted in OLV-1, OMMV and PoNV ORF3, which may have a membrane anchoring function.

ORF4 is the CP gene encoding a 24–30 kDa protein, the building block of the capsid. Necro-like virus CP was shown to be a multifunctional protein: besides encapsidation, it is required also for symptom modulation and efficient systemic virus spreading in the host and in the environment, since it has been reported to interact with the zoospores of the fungus *Olpidium brassicae*. Moreover, TNV-D CP was shown to modulate virus replication, since its deletion enhances virus RNA accumulation, whereas BBSV CP is able to interact with viral and host factors during virus replication. Silencing suppression ability was shown for OMMV CP, which acts coordinately with the ORF4 p6 product.

No experimental evidence is available for the expression of TNV-A ORF5.

Intraspecific Relationships

Necro-like viruses are serologically distinguishable from one another. Some are unrelated (e.g., LWSV with TNV-A and TNV-D), whereas others share antigenic determinants that result in weak relationships. Serological relationships are independent from whether viruses belong to genera *Alphanecrovirus* or *Betanecrovirus*. This is the case of OLV-1 (*Alphanecrovirus*) which is distantly related (serological differentiation index from 6 to 9) with both TNV-A (*Alphanecrovirus*) and TNV-D (*Betanecrovirus*), and of OMMV and PoNV (*Alphanecrovirus*) which are serologically related with TNV-D (*Betanecrovirus*).

The level of molecular similarity varies very much with the viral species. The RdRp sequence identity is high within the members of the genera *Alphanecrovirus* or *Betanecrovirus*, respectively, but low between alphanecroviruses and betanecroviruses. Thus, TNV-A, OLV-1, OMMV and PoNV share 86%–92% sequence identity with one another in the RdRp at the amino acid level. Likewise, TNV-D, BBSV and LWSV share 57%–69% sequence identity with one another, but sequence identity ranges from only 32%–36% between members of the two genera.

MP1 aa sequences show high identities among each other alphanecrovirus (66%–90%) and betanecrovirus (39%–49%), respectively, but only 6%–23% identity if alphanecroviruses are compared with betanecroviruses. Similarly, alphanecrovirus MP2 amino acid sequences share 95%–100% identity, but they show only 10%–26% identity with betanecrovirus MP2 sequences. Members of the genus *Betanecrovirus* share 39%–47% sequence identity with one another at the MP2 amino acid level.

The CP sequences of both alpha- and betanecroviruses are related and share 26%–86% sequence identity. OMMV (genus *Alphanecrovirus*), a putative recombinant between TNV-D and OLV-1, shows the highest CP sequence identity (86.2%) with that of TNV-D (genus *Betanecrovirus*), which may account for the cross reactivity with this virus, and 91.2% identity at the amino acid level with the RdRp of OLV-1.

Satellites

Satellites are subviral agents depending on the presence of a helper virus for replication, movement and transmission. Satellite nucleic acids are encapsidated by the helper virus encoded coat protein, whereas satellite viruses are able to encode for their own capsid protein.

Three satellite viruses are associated with necro-like viruses: Satellite tobacco necrosis virus (STNV)-1, STNV-2 and STNV-C. They all belong to the genus *Albetovirus* (from alphanecrovirus, betanecrovirus, tobacco) (realm *Riboviria*) and are classified as representative isolates of the species *Tobacco albetovirus 1*, *Tobacco albetovirus 2* and *Tobacco albetovirus 3*, respectively. STNV-1 and -2 are associated with the replication of TNV-A, whereas STNV-C is associated with TNV-D. The association of the satellite virus with its helper virus is specific, since no heterologous helpers have been reported to support STNV replication. STNV-1, -2 and -C are transmitted in association with TNV-A or -D by the fungus *Olpidium brassicae*, using the same mechanism as the helper virus.

The three STNV have isometric particles *c.* 17 nm in diameter, sedimenting as a single component with a coefficient of 50S, for which the crystal structure has been determined. The capsid is constructed with 60 identical subunits *c.* 21–22 kDa in size, arranged in a *T* = 1 lattice, and contains a single-stranded, positive-sense RNA molecule 1221–1245 nt in size. STNV RNA accounts for *c.* 20% of the particle weight, and comprises a single ORF encoding the CP. Similarly to the helper virus genome, STNV RNA is uncapped and lacks a 3′ poly(A) tail. The 5′ and 3′ untranslated regions share limited identity (47% and 36% for STNV-C) with the corresponding regions in the cognate virus genome, but are interchangeable between satellite and helper viruses, thus suggesting that they share also the same replication mechanism. Short stem-loop structures are responsible for the specific packaging of the satellite virus RNA in its own CP. The first 3′-translational enhancer domain (TED) ever characterized is present downstream the CP encoding sequence in the 3′-untranslated region of STNV RNA, which is able to function as a 5′ cap and to interact with the eIF4F complex. Long-distance interactions between the 3′-TED and a 38 nt stretch in the 5′ UTR are important in enhancing and regulating the translation of satellite virus RNA.

The satellite virus genome contains signals for the correct packaging and specific assembly of the virus particles. The CP sequences of the three satellite viruses share 49%–62% sequence identity, but are different from any other viral protein, with the

exception of a limited sequence homology with the CP of Satellite maize white line mosaic virus (SMWLMV). The TNV satellite viruses are serologically distinguishable.

STNV-1 interferes to some extent with helper virus infections, ameliorating the TNV-induced symptomatology, probably because of competition for factors essential for shared replication mechanisms, for its presence in TNV inocula reduces slightly the virus concentration and the size but not the number of local lesions.

Whereas satellite viruses are not associated with any other member of the genus, BBSV supports the replication of a small, linear, single-stranded, noncoding satellite RNA 615 nt in size, which is encapsidated in the virions in monomeric or, more rarely, dimeric form. Monomers are thought to be produced from multimeric templates. BBSV satRNA enhances the aggressiveness of the helper virus for more lesions are produced on infected hosts when mixed inocula are used. Moreover, the effect of BBSV satRNA on the helper virus pathogenicity is further enhanced at low temperatures probably because of some satRNA interference with the expression of the host plant antiviral silencing genes.

Transmission and Host Range

All necro-like viruses are readily transmitted by mechanical inoculation to experimental herbaceous hosts, which usually react with necrotic local lesions, not followed by systemic infection. Under natural conditions, infection is often restricted to the roots. All necro-like viruses are transmitted through the soil, either by the chitrid fungus *Olpidium brassicae* (TNV-A, TNV-D, BBSV), or without the apparent intervention of a vector (OLV-1). Particles of species transmitted by *O. brassicae* are acquired by the vector from the soil where they are released from roots of infected plants through sloughing off epidermal cell layers and/or following decay of plant debris. Virions are bound tightly to the plasmalemma and the axoneme (flagellum) of the fungal zoospores and are transported inside the zoospore cytoplasm when the flagellum is retracted prior to encystment that precedes penetration in the host. The same mechanism is exploited by STNV to gain entrance into both vector and host. Since necro-like viruses and their satellites (STNV and BBSV satRNA) multiply in the plant cells but not in the fungal plasmodium, zoospores released from infected roots are virus-free. Transmission can therefore occur only if they come again in contact with and adsorb virus particles.

Seed transmission of necro-like viruses has not been reported, except for OLV-1, which was detected in the integuments and internal tissues of 82% olive seeds, and transmitted to 35% of the seedlings. Pollen transmission has not been reported for necro-like viruses so far.

The natural host range and geographical distribution of necro-like viruses varies with the species. Thus, TNV-A and TNV-D are ubiquitous and infect a wide range of cultivated and wild plants. OLV-1 was recorded from olive in several Mediterranean countries, citrus in Turkey, tomato in Poland and tulip in Japan; OMMV from olive in Portugal, spinach in Greece and tulip in the Netherlands; PoNV, the most recently characterized alphanecrovirus, was found on potato in UK; BBSV was recorded from beet in China, LWSV from leek in France.

Cytopathology

Necro-like viruses replicate very actively in their hosts, which translates into the production of a large number of virus particles in infected cells of all tissue types, including vessels. Virions are either scattered in the cytoplasm, gathered in bleb-like evaginations of the tonoplast into the vacuole, or arranged in crystalline arrays of various sizes. STNV particles can also give rise to crystals that can be found in the same cells along with those of the helper virus. Cells infected by TNV and OLV-1 also contain two types of inclusions, that is, clumps of electron-dense amorphous material resembling accumulations of excess CP and fibrous bundles made up of thin filaments with a helical structure. In OLV-1 infected cells, these bundles were identified as accumulations of the 8 kDa movement protein expressed by ORF2. The same protein and the 6 kDa movement protein coded for by ORF3 were detected by immunogold labeling near plasmodesmata.

Cytoplasmic clusters of membranous vesicles with fibrillar material, derived from the endoplasmic reticulum or lining the tonoplast, were observed in cells infected by OLV-1 and LWSV.

Crown Copyright © 2021 Published by Elsevier Ltd. All rights reserved.

Glossary

Lectin Protein that has the ability to bind carbohydrates (sugars).

Odonstyle Anterior section of the stylet of a longidorid nematode. The odonstyle consists of a needle-like mouth spear used to penetrate plant root cells.

Odontophore Posterior section of the stylet of a longidorid nematode. The odontophore is located at the

base of the nematode mouth. Stylet protractor muscles are attached to the odontophore.

Triradiate lumen Posterior region of the lumen (or food channel) of the esophagus of a longidorid nematode. The triradiate lumen is located in a muscular bulb at the base of the esophagus. The radial muscles attached to the triradiate lumen are used for food ingestion.

Introduction and Historical Perspective

Nepoviruses were among the first 16 groups of viruses recognized by the International Committee on Taxonomy of Viruses (ICTV). The name stands for nematode-transmitted viruses with polyhedral particles. From its origin as the “nepovirus group”, it became the genus *Nepovirus* within the family *Comoviridae*, which also included the genera *Fabavirus* and *Comovirus*. Taxonomic updates later led to the dissolution of the family *Comoviridae* and the creation of the family *Secoviridae*, to which the genus *Nepovirus* is assigned as part of the sub-family *Comovirinae*. Although nematode transmission was one of the original defining characteristics of the genus *Nepovirus*, the primary criteria for inclusion of viruses in the genus are now the structure of the RNA genome and of the particles and phylogenetic relationships. As a result, not all viruses belonging to the genus *Nepovirus* are nematode transmitted ([Table 1](#)), and some nematode-transmitted polyhedral viruses that were originally classified as nepoviruses, have been reclassified (e.g., *Strawberry latent ringspot virus*, currently an unassigned species within the family *Secoviridae*). As of 2019, there are 40 recognized nepovirus species ([Table 1](#)). Nepoviruses cause a variety of diseases of economic importance, notably on grapevine, fruit trees, small fruits and other horticultural crops.

Taxonomy, Phylogeny, and Evolution

The genus *Nepovirus* belongs to the sub-family *Comovirinae* (also including the genera *Comovirus* and *Fabavirus*), family *Secoviridae* (encompassing the genera *Cheravirus*, *Sadwavirus*, *Torradovirus*, *Sequivirus* and *Waikavirus*, in addition to the sub-family *Comovirinae*), order *Picornavirales* (consisting of six families including *Secoviridae* and *Picornaviridae*), realm *Riboviria*. Nepoviruses share several characteristics in common with other members of the order *Picornavirales*: the small polyhedral viral particles, the positive-strand RNA genomes that are polyadenylated at their 3' end and linked to a small genome-linked protein (VPg) at their 5' end, the production of mature viral proteins by proteolytic cleavage of large polyproteins, and the conserved signature sequences and order of viral replication protein domains within the polyproteins including the nucleotide triphosphate-binding protein (a putative helicase abbreviated either as NTB or as Hel in the literature), the VPg, a chymotrypsin-like protease (Pro), and the RNA-dependent RNA polymerase (Pol). Nepoviruses have a bipartite genome with each RNA encoding one large polyprotein, a property they share with several other members of the family *Secoviridae* (referred to as secovirids from hereon). Similar to other secovirids with a bipartite genome, the RNA1 polyprotein includes the domains for the replication proteins and the RNA2 polyprotein contains the domains for the movement protein (MP) and coat protein (CP). Nepoviruses encode a single large coat protein of 53–60 kDa, a characteristic they only share with a few other secovirids (e.g., *Strawberry mottle virus*). In contrast, other secovirids have either two (*Comovirus*, *Fabavirus*, *Sadwavirus*) or three (*Cheravirus*, *Torradovirus*, *Sequivirus*, *Waikavirus*) coat proteins. In phylogenetic trees based on the Pro-Pol amino acid sequence, which is defined by the sequence between the conserved catalytic cysteine (or serine, see below) of the Pro domain and the conserved GDD motif of the Pol domain, nepoviruses branch together as a sub-branch within a larger branch corresponding to the sub-family *Comovirinae* ([Fig. 1](#)). Nepoviruses are genetically very diverse, more so than most other genera in the family. Phylogenetic trees based on different protein domains are not always congruent ([Fig. 1](#)). This is likely due to reassortment between the two viral RNAs and/or recombination events that have contributed to the evolution of nepoviruses. Nepoviruses have been divided into three subgroups (A, B and C) based on the length and packaging of RNA2, and serological properties ([Table 1](#)). These subdivisions may need to be further refined in the future. Indeed, while subgroup B nepoviruses confidently branch together in the phylogenetic trees based on the Pro-Pol or CP amino acid sequences, subgroup C nepoviruses only cluster together in the CP phylogenetic tree and subgroup A nepoviruses do not consistently group together ([Fig. 1](#)).

^aOnly cases for which a specific association with a nematode vector has been verified experimentally are listed.^bGenBank accession numbers are listed. A (+) symbol indicates that a type B satellite is known to be associated with the virus but has not been sequenced.

Fig. 1 Phylogenetic analyses of nepoviruses and other members of the family *Secoviridae*. The amino acid sequence of the CP or Pro-Pol domains from recognized species within the family *Secoviridae* were aligned using Clustal W. Phylogenetic analyses were conducted using the maximum likelihood method as implemented in MEGA 6. *Enterovirus C* (EVC, genus *Enterovirus*, family *Picornaviridae*) was used as an outgroup. The results of 1000 bootstraps are shown for each node (only values above 50% are shown). A scale for the genetic distance is shown below the trees. Nepovirus acronyms are as listed in Table 1, the letter in parenthesis after each acronym represents the subgroup. Branches corresponding to genera other than nepoviruses were collapsed. The *Sadwavirus* branch includes *Satsuma dwarf virus* (the only recognized species of the genus) and four related species that are unassigned within the family *Secoviridae* (*Strawberry mottle virus*, *Black raspberry necrosis virus*, *Chocolate lily virus A* and *Dioscorea mosaic associated virus*). SLRSV: *Strawberry latent ringspot virus*, an unassigned species in the family *Secoviridae*. StPV: *Stocky prune virus*.

Fig. 2 Electron micrograph depicting purified nepovirus particles and cytopathological structures typical of nepovirus-infected cells. (A) Purified ToRSV particles in negative staining. Note the empty particle (T-particle) which is penetrated by the negative stain (arrow). (B) Proliferation of membrane vesicles observed in the vicinity of the nucleus (Nc) in ToRSV-infected cells. (C) Tubular structures containing virus-like particles accumulating near the cell wall (CW) in PRMV-infected cells. (D) Tubular structure traversing the cell wall in ArMV-infected cells. Bars represent 25 nm in panel A and 200 nm in panels B–D.

Virion Structure

Nepoviruses have isometric particles of 26–30 nm in diameter with sharp hexagonal outlines (Fig. 2(A)). Equilibrium centrifugation in CsCl of purified virus particles typically reveals the presence of three types of particles. T-particles sediment at 50S and do not contain an RNA molecule. In electron microscopy, these empty particles are penetrated by a negative stain. B-particles sediment at 115–134S and contain a single molecule of RNA1. In the case of sub-group A nepoviruses, B-particles can also contain two molecules of RNA2. M-particles sediment at 86–128S and contain a single molecule of RNA2. M- and B-particles of sub-group C nepoviruses are often difficult to separate due to the larger size of RNA2.

Nepovirus particles contain 60 molecules of the single CP. The crystal structure of virus particles was solved for TRSV, GFLV and ArMV (see Table 1 for acronyms). The structure of BRV particles was also inferred by cryo-electron microscopy. The pseudo T=3 structure is similar to that of comoviruses and picornaviruses. The CP contains three functional domains. Each functional domain corresponds to one of the three smaller CPs found in picornaviruses and consists of eight β -strands that form a β -barrel. Comoviruses also share a similar structure with one large CP containing two β -barrels and one small CP with a single β -barrel. The N-terminal region of the CP is buried inside the particle while the C-terminal region of the CP is exposed to the outside of the particle. In many nepoviruses, a small fragment of the C-terminus of the CP is cleaved off from the virions at late stages of infection, although the biological function of this cleavage is not known. Several loops connecting the β -strands are exposed to the surface of the particle and interact with the viral movement protein to support cell-to-cell movement or with vector receptors to enable transmission. The mechanism of encapsidation is not well-characterized, but the presence of empty particles with structures similar to full particles suggests that presence of the viral RNAs is not strictly required to initiate capsid assembly.

Genome Organization and Function of Viral Proteins

The genomic organization of a representative virus from each subgroup is shown in Fig. 3. The C-terminal protein domains of the polyproteins are conserved amongst nepoviruses, while the N-terminal regions of the polyproteins are more variable. The C-terminal portion of the RNA1 polyprotein contains the NTB, VPg, Pro and Pol domains, which are implicated in viral RNA replication and regulation of polyprotein processing. Identification of cleavage sites upstream of NTB defined two protein domains in the N-terminal region of the ToRSV and ArMV RNA1 polyproteins, termed X1 and X2. Putative cleavage sites at corresponding positions were found in the RNA1 polyproteins of other nepoviruses. Thus, the presence of two protein domains upstream of NTB is likely a common feature of nepovirus RNA1 polyproteins, which is not shared by comoviruses or fabaviruses. The X2 protein domain is highly hydrophobic, shares conserved sequence motifs with the 32 kDa protein of comoviruses and has been suggested to play a role in the assembly of replication complexes. The X1 domain shows a high degree of sequence diversity amongst nepoviruses and its function is unknown. Because RNA1 encodes all the essential replication proteins, it is able to replicate in single plant cells without the assistance of RNA2. The RNA2 polyprotein includes the domains for the CP and MP at its C-terminus and one or two additional protein domains at its N-terminus: the single 2a domain for subgroup A and B nepoviruses and the two X3 and X4 domains for ToRSV, a subgroup C nepovirus. The GFLV 2a protein plays a role in the replication of RNA2. The function of X3 and X4 is not known. Both RNA1 and RNA2 are required for cell-to-cell and systemic movement of the virus in the plant. Infectious cDNA clones have been produced for subgroup A (GFLV, ArMV, RpRSV, TRSV) and subgroup B (TBRV) nepoviruses, allowing reverse genetic experiments for these viruses.

Fig. 3 Genomic organization of representative nepoviruses of subgroup A (*ArMV*), B (*BRSV*) and C (*ToRSV*). Each RNA is represented with the covalently attached VPg (pink circle) and the polyA tail (A_n). The coding regions are represented by the boxes. Cleavage sites confirmed by *in vitro* processing experiments or by the detection of viral proteins in infected plants are indicated by the continuous vertical lines. Putative cleavage sites that have not been confirmed experimentally are shown with dashed lines. Dipeptide sequence of confirmed or putative (in parenthesis) cleavage sites are indicated above each line. Thick bars below each RNA indicate regions with high degree of sequence identity between RNA1 and 2 (black for regions with near 100% sequence identity and gray for regions with 75%–83% sequence identity).

Each RNA includes untranslated regions (UTR) at its 5' and 3' ends. The 5' UTR is 70–300 nucleotides (nts) long while the 3' UTR varies in length from 200 to 400 nts for subgroup A and B nepoviruses to 1300–1600 nts for subgroup C nepoviruses. RNA1 and 2 often share regions of complete or partial sequence identity in the UTRs (Fig. 3). For example, the 5' UTRs of ToRSV RNA1 and 2 share a region of 100% sequence identity which extends into the coding region. On the other hand, the 5' UTRs of the BRV RNAs share only 78% sequence identity and do not extend beyond the UTRs. The 3' UTRs of RNA1 and 2 are often nearly identical, especially those of subgroup C nepoviruses. Conservation of sequence identity in the UTRs has been attributed to recombination between the two RNAs occurring during replication of the viral RNAs and/or to selection pressure.

Production of Viral Proteins: Translation and Polyprotein Processing

The viral RNAs are polyadenylated but are not capped, requiring a cap-independent translation mechanism. Studies on BRV RNAs suggested that long-distance interaction between the 5' and 3' UTRs (possibly directed by sequences in the loops of putative stem-loop structures) is required for efficient translation of the viral RNAs. In addition, the polyA tail enhances translation efficiency. Further work will be necessary to elucidate the exact mechanism of BRV RNAs translation, in particular the requirement for plant translation factors, and to determine whether other nepoviruses utilize similar or distinct mechanisms to translate their RNAs.

Nepoviruses encode a single protease which is responsible for processing the two polyproteins. Nepovirus Pros are related to the 3C-Pro of picornaviruses. The catalytic triad normally consists of a histidine, glutamic acid and cysteine, although the Pros of a few subgroup C nepoviruses have a serine instead of the cysteine as the third component of the triad. Proteases also contain a substrate-binding pocket that determines their cleavage site specificity. Similar to picornaviruses, a conserved histidine is found in the substrate-binding pocket of all subgroup C nepovirus Pros characterized so far and of one subgroup A nepovirus Pro (MMLRaV). The cleavage sites recognized by these Pros normally include a glutamine, asparagine or aspartate at the -1 position. This is similar to the conserved glutamine or glutamate found at the -1 position of picornavirus cleavage sites. However, there are reported exceptions, including a characterized cleavage site recognized by the BLSV Pro with a cysteine at the -1 position and several putative cleavage sites of subgroup C nepoviruses with a histidine at the -1 position. The Pros of subgroup A and B nepoviruses contain a leucine instead of a histidine in their substrate-binding pocket and recognize a variety of cleavage sites that have lysine, cysteine, arginine or glycine at the -1 position. Thus, nepovirus proteases have very diverse specificities, often making the prediction of cleavage sites difficult.

The RNA1 polyprotein is cleaved predominantly intra-molecularly (*cis*-cleavage). The RNA2 polyprotein is cleaved *in trans* by the Pro. The processing cascade results in the release of mature proteins and stable processing intermediates containing two or more protein domains. These intermediate polyproteins accumulate in infected plant cells and may have different activities from the mature proteins. In ToRSV-infected cells, several polyprotein intermediates containing the NTB domain are detected in addition to the mature NTB protein. In BRSV-infected cells, an intermediate containing the Pro and Pol domains accumulates rather than the mature Pro and Pol proteins. This suggests preferential recognition of some cleavage sites by the viral Pro. Slow release of mature proteins by processing of stable intermediates at suboptimal cleavage sites provides a regulatory mechanism to control the accumulation of specific proteins during the replication cycle. In fact, the activity of the Pro itself is regulated by its release from larger polyprotein precursors. Indeed, the mature Pro of GFLV and ToRSV processes the cleavage sites of the RNA2 polyprotein more efficiently than the VPg-Pro precursor.

Viral RNA Replication

Infection of plant cells by nepoviruses results in membrane proliferation and the formation of membrane vesicles (Fig. 2(B)). The use of cerulenin, an inhibitor of *de novo* phospholipid synthesis, has confirmed that membrane proliferation is required for the replication of GFLV RNAs. Brefeldin A also inhibits GFLV replication suggesting a requirement for intact vesicle trafficking between the endoplasmic reticulum (ER) and the Golgi apparatus. The replication complexes of two nepoviruses (GFLV and ToRSV) were shown to co-localize with ER-derived membranes in infected cells. Double-strand RNA replication intermediates, viral replication proteins and replication activity are associated with the membrane-bound complexes. GFLV VPg antibodies were used to isolate membrane vesicles that had a rosette-like structure similar to that associated with picornavirus replication complexes.

As shown for ToRSV, the mature NTB protein and the intermediate NTB-VPg and X2-NTB-VPg polyproteins co-fractionate with the replication complex, suggesting that they act as membrane anchors for the replication complex. The NTB protein contains two membrane-binding domains: a C-terminal transmembrane domain and a putative N-terminal amphipathic helix. The ToRSV X2 protein also contains several transmembrane helices that traverse the ER membrane. Other replication proteins (Pro, Pol or intermediate polyproteins containing these domains) are soluble when expressed individually but are found in association with the membrane-bound replication complex in infected cells. Thus, they are probably brought to the replication complex either as part of a larger polyprotein that includes the NTB domain or through protein-protein interaction with the viral membrane anchors. By analogy with picornaviruses, the VPg protein may act as a primer for viral replication, although this has not been demonstrated experimentally for nepoviruses. The GFLV RNA2-encoded 2a protein is also

associated with the replication complex. The 2a protein is required for the replication of RNA2 but not RNA1 and probably interacts with RNA1-encoded replication proteins.

Cell-to-Cell and Systemic Movement in the Plant

Nepovirus-infected cells are characterized by the presence of tubular structures containing virus-like particles in or near the cell wall (Fig. 2(C) and (D)). These tubules are similar to the ones found in comovirus-infected cells and have been suggested to direct the cell-to-cell movement of intact virus particles. The viral movement protein is a structural component of the tubular structure. Expression of the GFLV MP alone is sufficient to induce the formation of empty tubular structures in intact plant cells or in protoplasts. In the latter case, tubular extensions are found projecting from the surface of the protoplasts, a phenomenon also induced by comovirus MP. The GFLV MP is an integral membrane protein. The secretory pathway and the cytoskeleton are involved in the intracellular targeting of the GFLV MP from its site of synthesis (probably in association with the ER-bound replication complex) to specific foci in the cell wall where it assembles into tubules. GFLV cell-to-cell movement also requires myosin-motor plant proteins, which may assist in transporting other plant proteins to the plasmodesmata to initiate the formation of the MP tubules. By analogy with comoviruses, it is likely that an interaction between MP and CP is necessary to enable nepovirus cell-to-cell movement. A surface-exposed region of the CP and the C-terminal region of the MP are probably involved in this interaction. Long-distance movement of TRSV occurs through the phloem resulting in the invasion of most tissues of the plant including meristematic tissues. The virus probably reaches the phloem through cell-to-cell movement from inoculated cells to phloem sieve tubes.

Host Range, Symptom Determinants and Interaction With Plant Defense Responses

Most nepoviruses have a wide host range that includes woody and herbaceous hosts. In nature, many hosts remain symptomless while others display symptoms such as necrotic or chlorotic rings which can appear as concentric rings (ringspots) or lines. Other symptoms can include leaf flecking and mottling, vein necrosis, plant stunting and in some cases death. Common experimental hosts used for virus propagation are *Chenopodium quinoa* (in which most nepoviruses induce obvious symptoms), *C. amaranticolor*, *C. murale*, *Cucumis sativus*, *Nicotiana clevelandii*, *N. benthamiana*, *Petunia hybrida* and *Phaseolus vulgaris*. The intensity of symptoms produced by nepovirus infection depends on the specific virus-host combination and on environmental conditions.

In many herbaceous hosts and in particular in *Nicotiana* species, symptoms develop on the inoculated leaves and on the first upper systemic leaves. Later in infection, new leaves remain free of symptoms although the virus is present. This phenomenon is termed symptom recovery. Recovered leaves of nepovirus-infected plants often show reduced concentration of viral RNAs and this has been attributed at least in part to the induction of the plant antiviral RNA silencing. Recovered leaves are also resistant to reinfection in a sequence-dependent manner. In the *Nicotiana benthamiana*-ToRSV interaction, the establishment of symptom recovery depends on the specific isolate and also on the growth temperature (Fig. 4). The onset of symptom recovery from a severe ToRSV isolate is not accompanied with a significant reduction of viral RNA levels. However, translation of the viral RNAs is suppressed limiting the accumulation of viral proteins and encapsidation. It has been hypothesized that the low nepovirus titers typically found in late stages of infection contribute to their ability to escape plant surveillance systems and invade meristematic tissues.

When they occur, necrotic symptoms share characteristics of a hypersensitive response (HR) normally induced by activation of plant dominant resistance gene. Although the virus can be restricted to local necrotic lesions developing on inoculated leaves in some hosts, the HR-like response often fails to contain the virus and systemic infection is observed, which may be followed by recovery or not. The plant genetic determinants of this HR-like response have been characterized in the *Arabidopsis thaliana*-TRSV interaction. Most *A. thaliana* ecotypes are tolerant to TRSV and do not display visible symptoms. However, the lethal systemic necrosis induced by TRSV in some ecotypes was linked to a dominant mutation in the TTR1 resistance gene. Viral symptom determinants have also been identified in a few interactions. In the *Nicotiana occidentalis*-GFLV interaction, construction of chimeric clones between two isolates identified the 2a protein as the elicitor for the necrotic HR-like response. Using a similar approach, a single amino acid in the GFLV Pol was found to determine vein clearing symptoms in *N. benthamiana*.

Transmission

Many nepoviruses are transmitted by soil dagger nematodes belonging to the genera *Xiphinema*, *Longidorus* or *Paralongidorus* in the order *Dorylaimida*, family *Londigoridae*. The nematodes feed ectoparasitically on the roots using long mouth stylets. There is no evidence that nepoviruses replicate in the nematodes. The acquired viruses remain transmissible for varying periods of time (9 weeks for *Longidorus* species and up to 4 years for *Xiphinema* species), suggesting different modes of retention and release of the virus. Because of the restricted movement of the nematodes through the soil, the spread of nematode-transmitted nepoviruses through an infected field is slow and often occurs in patches. The interaction between nepoviruses and nematodes is

Fig. 4 Symptom recovery in ToRSV-infected *Nicotiana benthamiana* plants. Plants inoculated with a severe (Rasp1) or mild (GYV) isolate of ToRSV were grown at either 27°C or 21°C. GYV-infected plants recover from infection at both temperature, while Rasp1-infected plants only recover from infection at 27°C. Detached inoculated leaves (I), upper symptomatic leaves (S) or recovered leaves (R) are shown at the indicated days post-infection (dpi). The lower panel compares plants that were mock-inoculated to plants infected with the two isolates at 20 dpi after growth at 27°C (left) or 21°C (right). Modified from Ghoshal and Sanfacon, 2014. Temperature-dependent symptom recovery in *Nicotiana benthamiana* plants infected with tomato ringspot virus is associated with reduced translation of viral RNA2 and requires ARGONAUTE 1. *Virology* 456–457, 188–197. Paudel *et al.*, 2018. Expression and antiviral function of ARGONAUTE 2 in *Nicotiana benthamiana* plants infected with two isolates of tomato ringspot virus with varying degrees of virulence. *Virology* 524, 127–139. Both under Crown Copyright.

usually specific with only one or two species of nematodes transmitting a given nepovirus (Table 1). In the case of GFLV, the viral determinant for the specificity of nematode transmission has been mapped to the CP, in particular a positively charged pocket exposed to the surface of virus particles. It is not known whether specific nematode receptors recognize the viral CP. Earlier studies suggested that carbohydrates may be involved in the retention of ArMV particles in its vector. However, further experiments will be required to determine if the viral coat protein has lectin properties. It has been suggested that pH changes may be involved in the release of viral particles from their site of retention within the nematode. Nepoviruses transmitted by *Longidorus* species are usually associated with the odontostyle, while viruses transmitted by *Xiphinema* species are found associated with the cuticle lining the lumen of the odontophore and the esophagus. Interestingly, while TRSV and ToRSV are both transmitted by *X. americanum*, immunofluorescence labeling of these viruses in the nematode vector revealed different sites of retention. TRSV is retained predominantly in the lining of the lumen of the stylet extension and the anterior esophagus, while ToRSV is localized only in the triridiate lumen. Although the predominant vector for transmission of TRSV is a nematode, possible aerial vectors have been suggested including *Thrips tabaci* and *Epitrix hirtipennis* (flea beetle). The importance of these vectors in natural epidemics of TRSV-induced diseases needs to be confirmed. A recent study also reported detection of TRSV double-strand RNA replication intermediates in bees, suggesting viral replication. However, TRSV is not transmitted by bees and the biological relevance of this observation, including its possible association with bee decline, is not clear. Other nematode-transmitted nepoviruses do not have known aerial vectors. BRV is transmitted by the eriophyid gall mite of black currant (*Cecidophyopsis ribis*) and possibly other *Cecidophyopsis* species but not by nematodes. Plant-to-plant transmission can occur rapidly (in only 4 h). Virus particles have not been found inside mites suggesting that the transmission may be non-persistent or semi-persistent. Two surface-exposed amino acid triplets are conserved between the CP of BRV and other mite-transmitted viruses from unrelated genera, suggesting that they may play a role in the interaction between the virus and its vector. However, this remains to be determined experimentally.

Seed transmission has been reported for most but not all nepoviruses. For example, BRV is apparently not seed transmitted. Infection can occur through the ovule or the pollen, although nepovirus-infected pollen may not compete effectively with healthy pollen. An exception to this is BLMoV and CLRV, which are efficiently transmitted by pollen. Honeybees likely contribute to the pollen transmission of BLMoV by increasing the movement of infected pollen. Many nepoviruses are readily transmitted through grafting and mechanical inoculation. The propagation of infected seed and plant stocks plays an important role in the long-

distance movement of nepoviruses. Because many nepoviruses have a wide host range including common weeds, dormant weed seeds may provide a reservoir for the virus in the field.

Population Structures: Quasi-Species, Satellite RNAs and Defective-Interfering RNAs

Examination of nepovirus isolates recovered from different hosts or geographic locations has revealed a degree of sequence diversity of 2%–20% at the nucleotide level. Isolates can also differ in the length of their RNAs with the RNA2 polyprotein N-terminal domains being the most variable, as shown for the GFLV and ArMV 2a protein and the ToRSV X4 protein. Evidence for recombination and reassortment between viral RNAs is well-documented resulting in the emergence of new viral strains or species, although interspecies recombination has so far only been reported among closely related nepovirus species. Mixed infections between viral isolates and/or closely related species frequently occur in the field. In agreement with the quasi-species model, detailed analyses of GFLV population structure highlighted the presence of a few predominant variants along with other minor variants. An ArMV field isolate was shown to contain two species of RNA2, each encoding a distinct polyprotein. It is possible that co-existing variants act synergistically to facilitate infection or determine symptoms but this has not been tested experimentally. Analysis of a number of CLRV isolates revealed that the degree of diversity is defined primarily by the host rather than the geographic location. This is an unusual situation among plant viruses and may reflect the fact that this virus is pollen-transmitted.

Two classes of satellite RNAs (satRNAs) have been found in association with some nepoviruses ([Table 1](#)). SatRNAs depend on the helper virus for their replication and are encapsidated in virus particles. Type B satRNAs are 1100–1500 nts in length. They are linked to a VPg molecule at their 5' end, polyadenylated at their 3' end and encode a non-structural protein which is essential for their replication. The exact function of the encoded protein is not known but it has been suggested that it interacts with the viral replication complex. The 5'-ends of type B satRNAs often have short sequence motifs that are identical or nearly identical to the 5' ends of the viral RNAs and are likely recognized by the viral replication complex. One or several copies of type B satRNAs are packaged in the viral particles, either alone or together with one molecule of RNA2. As a general rule, type B satRNAs are replicated specifically by the virus with which they are associated although there are exceptions (e.g., the replication of GFLV satRNA is supported by ArMV). Type B satRNAs are usually found in low concentration and do not affect significantly the replication of the helper virus or the symptomatology.

Type D satRNAs are less than 500 nts long. They are not linked to a VPg molecule or polyadenylated and do not encode a protein. Type D satRNAs are encapsidated as monomeric or multimeric linear molecules. A circular form of the molecule is present in infected cells and serves as the polymerase template for replication through a rolling circle mechanism. The multimeric linear forms produced during replication are cleaved in an autocatalytic reaction which allows the release of linear monomers. These monomers are circularized to form new templates of positive or negative polarity. Type D satRNAs have been shown to either attenuate (TRSV) or intensify (ArMV) symptoms associated with the helper virus.

TBRV is the only nepovirus reported to be associated with defective-interfering RNAs (diRNAs). These 400–500 nts RNAs are derived exclusively from RNA1 and are probably produced during viral RNA replication. Presence of the diRNAs was associated with attenuated symptoms and reduced virus accumulation in some hosts. However, further work will be necessary to confirm the biological significance of the diRNAs and to determine whether they are also observed in other nepovirus-plant pathosystems.

Diseases, Economic Considerations and Control

Nepoviruses cause a wide range of diseases on a variety of crops including: grapevine, small fruits such as strawberry, raspberry, blueberry, black currant and red currant, fruit trees such as peach, apricot, almond, cherry, plum, walnut and apple, and other horticultural crops including but not limited to hop, soybean, potato, beet and tobacco. Many nepoviruses also induce diseases in ornamental species. Most nepoviruses are restricted geographically by the natural distribution of their nematode vector. An exception to this is GFLV which has been disseminated worldwide along with its vector. GFLV is the most significant nepovirus at the economic level and can reduce yield in grapevine by as much as 80%. Other nepoviruses can cause significant diseases where they occur.

Nepoviruses are mainly controlled through the removal of infected plants and replanting with resistant cultivars (when available) or with virus-free certified plant material. Weed control can reduce potential reservoirs for further nepovirus infection. In the case of nematode-transmitted nepoviruses, soil can be treated with broad-spectrum fumigant nematicides. However, because nematode populations can occur at considerable depths in the soil (one meter or more), fumigation rarely completely eliminates plant parasitic nematodes from a site and population densities typically return to pre-fumigation levels within a few years in the presence of a suitable host. Further, many fumigant nematicides are now banned due to their toxicity.

Few natural sources of resistant cultivars are available for nepoviruses. Transgenic expression of small regions of the viral genome was shown to induce the plant antiviral RNA silencing and provide virus resistance in herbaceous hosts (several nepoviruses) and in grapevine (GFLV). Broad spectrum resistance against a range of GFLV isolates was also obtained in *N. benthamiana* and in grapevine upon transgenic expression of camelid-derived heavy-chain only GFLV-specific antibodies. The characterization of plant factors essential for nepovirus infection combined with emerging gene editing approaches will likely provide new opportunities for generating non-transgenic nepovirus-resistant plants in the future.

Concluding Remarks

Although the infection cycle of nepoviruses is relatively well-understood, at least in herbaceous hosts, there are many outstanding questions. Many plant factors facilitating the translation, replication and movement of nepoviruses remain to be identified and/or characterized. Such plant factors may prove useful new targets for antiviral strategies, based on gene editing techniques. It will also be critical to evaluate the impact of nepoviruses and their complex populations (including the presence of multiple variants) in the field and to gain further insights into the emergence of virulent strains or new species. Additional research is needed to better understand the complex interaction between nepoviruses and various plant defense responses leading to the range of symptoms, including tolerance, symptom recovery and lethal systemic necrosis. Finally, evaluating the contribution of environmental factors on virus titers, disease severity and seed or vector transmission will also likely be a focus of future studies.

Glossary

Bunyavirales Order of viruses comprising species that have a segmented linear negative-sense RNA genome and a lipid envelope. The order includes 12 families:

Arenaviridae, *Cruliviridae*, *Fimoviridae*, *Hantaviridae*, *Leishbuviridae*, *Mypoviridae*, *Nairoviridae*, *Peribunyaviridae*, *Phasmaviridae*, *Phenuiviridae*, *Tospoviridae*, and *Wupedeviridae*.

Mononegavirales Order of viruses comprising species that have a linear, negative-sense RNA genome and a lipid envelope. The order includes 11 families: *Artoviridae*, *Bornaviridae*, *Filoviridae*, *Lispiviridae*, *Myonnaviridae*, *Nyamiviridae*, *Paramyxoviridae*, *Pneumoviridae*, *Rhabdoviridae*, *Sunviridae*, and *Xinmoviridae*.

Serpentovirales Order of viruses comprising 1 family, *Aspiviridae*, and 1 genus, *Ophiovirus*.

Introduction

The genus *Ophiovirus* is the only genus listed in the family *Aspiviridae* (formerly *Ophioviridae*), order *Serpentovirales*. The genus comprises plant-infecting virus species. In some cases ophioviruses are known to be the cause of well-known and “classical” major plant diseases, but in other cases the presence of the virus has not been linked to any specific symptom, due to almost invariable occurrence in mixed infections with other viruses. Ophioviruses occur in monocots and dicots, in vegetables, ornamentals, trees and shrubs, in the New and Old World, suggesting a well-adapted group of viruses. Where identified, the vectors of ophioviruses have proved to belong to *Olpidium* spp., soil-inhabiting chytrid fungi. Ophioviruses have been slow to emerge mainly because the virions are not easy to see in the electron microscope; indeed, the first ophiovirus particle was observed only in 1988 and its morphology understood in 1994. The genus name derives from the Greek word *ophis*, meaning snake, in reference to the serpentine appearance of the virus particles and the family name derives from the Latin word *aspis*, with the same meaning.

Taxonomy, Phylogeny and Evolution

There are currently seven species in the genus *Ophiovirus* (Table 1). The accepted species in the genus are: *Citrus psorosis ophiovirus* (the type species) (Citrus psorosis virus, CPsV), *Mirafiori lettuce big-vein ophiovirus* (Mirafiori lettuce big-vein virus, MLBVV), *Lettuce ring necrosis ophiovirus* (Lettuce ring necrosis virus, LRNV), *Ranunculus white mottle ophiovirus* (Ranunculus white mottle virus, RWMV), *Tulip mild mottle mosaic ophiovirus* (Tulip mild mottle mosaic virus, TMMMV), *Freesia sneak ophiovirus* (Freesia sneak virus, FreSV) and *Blueberry mosaic associated ophiovirus* (Blueberry mosaic associated virus, BlMaV). To date, the genomes of four species, MLBVV, CPsV, LRNV and BlMaV, are fully sequenced. For species demarcation within the genus, different criteria have been considered: the different coat protein (CP) sizes; absence of, or distant serological relationship between the CPs; differences in natural host range; and different number, organization, and/or size of genome segments. From available data, there is 95%–100%

Table 1 Virus members in the Genus *Ophiovirus* with relevant NCBI database accession numbers

Species (alternative name)	Acronym	Accession numbers ^a
Blueberry mosaic associated ophiovirus	BIMaV	NC036635, NC024476, NC036634
Citrus psorosis ophiovirus (Citrus ring-spot virus)	CPsV	NC006314, NC006315, NC006316
Freesia sneak ophiovirus (Freesia ophiovirus)	FreSV	MN365016, DQ885455
Lettuce ring necrosis ophiovirus	LRNV	NC006051, NC006052, NC006053, NC006054
Mirafiori lettuce big-vein ophiovirus (Mirafiori lettuce virus)	MLBVV	AF525933, AF525934, AF525935, AF525936
Ranunculus white mottle ophiovirus	RWMV	NC043389, AY542957
Tulip mild mottle mosaic ophiovirus	TMMMV	NC043390

^aComplete genome sequences are reported when available.

Fig. 1 Unrooted phylogenetic tree of selected ophiovirus isolates from different geographical origin, based on their NP amino acid sequences. The evolutionary history was inferred using the Neighbor-Joining method. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) are shown next to the branches. The evolutionary distances were computed using the Poisson correction. Evolutionary analyses were conducted in MEGA X. The TMMMV, RWMV and BIMaV AJR35847 nucleoprotein sequences analyzed are partial. Rectangles grouping isolates represent established viral species.

identity among complete CP aa sequences of isolates belonging to the same species detected in different world areas, in particular for MLBVV, CPsV, BIMaV and FreSV. The percentage of identity falls to 28%–59% for interspecies alignments, with the exception of the identity between MLBVV and TMMMV CP sequences, which is slightly above 80%, confirming the closeness of these two viruses. They are currently considered as two different species at least because of different host ranges; more information on TMMMV sequences is needed prior to any revision of their taxonomic position.

The percentage of identity/similarity between CP aa sequences may also be proposed as a further tool for species demarcation as several full sequences are now available. A phylogenetic tree based on alignment of representative CP aa sequences is shown in Fig. 1. CPsV and BIMaV, presently the only ophioviruses infecting perennial hosts with asexual means of propagation, are more correlated. These differences, if confirmed and reinforced, could lead to considering placement of these species in a different genus within the family Aspiviridae. RT-PCR amplification, using a pair of degenerate primers (see below), is currently a good tool for detecting and identifying official and potential new species within the genus, providing also indications of the taxonomic position of newly diagnosed isolates. The analysis of RdRp aa sequences shows the Aspiviridae family as a monophyletic group among negative-stranded RNA virus families of orders Bunyavirales and Mononegavirales, newly assigned to the order Serpentovirales. Recently, due to the wide use

Fig. 2 Negative contrast electron micrograph (uranyl acetate) of partially purified virion preparation from field lettuce showing big-vein symptoms. Note large and small ophiovirus particles. The bar represents 100 nm. Courtesy of RG Milne, IPSP-CNR, Torino, Italy.

of NGS technologies on complex samples, reports regarding aspivirus-like isolates in fungi note similarities of their RdRp protein sequences to those of LRNV and MLBVV, but further characterization is needed to assess their putative taxonomic position in the family *Aspiviridae*. Partial ophiovirus-like sequences have also been reported from NGS studies of *Plantago lanceolata*. Interestingly, a recent report describes the presence of endogenous viral elements (EVEs) putatively derived from an ophiovirus in the genome of the eelgrass *Zostera marina*. EVEs are sequences in eukaryotic genomes that are derived from the ancestral integration of viral sequences into germline cells; in this case the ancestral sequence is represented by the ophiovirus CP ORF; this finding, if confirmed, would extend the *Aspiviridae* host range to seagrasses and expand ophiovirus evolutionary history.

Virion Structure

The virions are naked filamentous nucleocapsids about 3 nm in diameter forming circularized structures of different lengths, presumably corresponding to the different lengths of the genomic segments. The virions appear to form internally coiled circles that in some cases can collapse into pseudolinear duplex structures (Fig. 2) and can be difficult to visualize in TEM assays due to a low contrast with the background. There is no evidence of a lipoprotein envelope and the mechanism underlining the apparent circularization of ophiovirus particles remains incompletely explained. Ophiovirus particles can be purified from infected plant tissue using differential centrifugation, clarifying the suspension using PEG6000 and sodium chloride, and density gradient ultracentrifugation. Particles are unstable in cesium chloride but the particle structure remains intact in cesium sulfate gradients (buoyant density is 1.22 g/cm³ for RWMV and MLBVV). Particle structure survives limited treatment with organic solvents and nonionic or zwitterionic detergents.

Genome Organization and Replication

The ophiovirus genome is ssRNA, 11.3–12.5 kb in size, divided into three or four segments (RNAs 1–4) of mainly negative sense. Positive- and negative-sense RNAs are individually encapsidated in ophiovirus particles, and the more abundant negative sense RNA is referred to as viral RNA (vRNA), while the complementary RNA will be described as viral complementary (vcRNA). The 3' termini of the vRNAs show sequences of 6–13 nt conserved within the RNAs of each species: A₇GUAUC for CPsV, A_{4–6}UAAUC for MLBVV, A₇GUAUCA and A₃UA₃GUAUCA for LRNV; A₂UAUC for BImaV; A₄UGUAUC for FreSV (preliminary results); these may be involved in the recognition of the RNAs by the RdRp. The 5' termini of BImaV RNAs were shown to fold into conserved stem-loop structures. These structures may be involved in packaging of genomic RNAs or in the long-distance interactions for transcription and replication. The pseudo-circularized appearance of ophiovirus particles suggests the presence of panhandle structures at genomic RNA ends, but no conclusive results were inferred for the four fully sequenced species. In CPsV, the first 12 nt of 5' end of vcRNAs were found almost identical in the three RNAs, but unexpectedly no identity among the three RNAs is found at their 3' ends, and no self-complementary panhandle structures between the 3' and 5' ends of each RNA could be hypothesized. In the case of MLBVV and LRNV, both 5' and 3' ends are highly or partially conserved among the four

^anot fully determined; – not detected.**Fig. 3** Genome organization of ophioviruses. The four genomic RNAs of MLBVV, the first ophiovirus to be full sequenced, are represented to scale. An RNA4 is not described in all species, see text and [Table 2](#) for details; v-RNA and vc-RNA indicate the viral and the viral complementary RNAs, respectively. Boxes indicate ORFs and the function of the encoded protein, if known, is reported.

viral RNAs but are not predicted to form panhandle structures; one hypothesis is that their RNAs ends fold into structures resembling the “corkscrew” conformation of RNA termini of members of the family *Orthomyxoviridae*, but this structure was not found for CPsV. Regarding BIMaV no complementarity was found between the 5′ and 3′ ends of each genomic RNA, as found for CPsV; in conclusion, alternative explanations for the pseudo-circular structure of ophiovirus particles are required.

The genome organization of ophioviruses is summarized in [Table 2](#) and [Fig. 3](#). All RNA segments have 5′ and 3′ untranslated regions. RNA1, the largest genome segment, is negative sense and contains two ORFs separated by an AU-rich intergenic region. The presence of two ORFs, the longest encoding the RdRp, with the same polarity in the largest RNA is a distinct genomic feature of *Aspiviridae* when compared to all other segmented negative-strand viruses. RNA2 contains one ORF in the negative strand in all four fully sequenced viruses. An additional minor ORF, in the virus-sense strand, is present for MLBVV, but to date there is no evidence for expression of the predicted 10 kDa protein. RNA3 contains one ORF in the vcRNA in all viruses, which has been identified as coding for the nucleocapsid protein. Up to now, an RNA4 has been found only in MLBVV and LRNV. Both encode a 37 kDa protein in the vc strand, with only MLBVV having a smaller (10.6K) ORF which lacks an initiation codon and is potentially expressed by a +1 translational frameshift near the 3′ end of the 37K ORF. A slippery sequence, GGGAAAU, can be recognized immediately in front of the UGA stop codon of the 37 kDa ORF. This unique feature of ORF positioning has been shown for two different isolates of MLBVV, and therefore seems not to be caused by cloning artifacts.

RNAs 1, 2, and 3 of the other partially sequenced species are similar in size to those described. No RNA4 has been found in CPsV, RWMV, BIMaV and TMMV, in spite of multiple NGS reactions, or PCRs using primers designed from the NGS data and conserved regions of the MLBVV/LRNV 37K proteins, which have been performed at least for BIMaV; its presence in FreSV is under study. Analysis for the presence of sub-genomic RNAs has not extensively been pursued for all species, even though several studies have used minus-strand and plus-strand probes in Northern blot hybridization using RNA extracted from infected tissues as well as virus particles, to obtain information regarding the polarity of encapsidated viral RNA. No subgenomic RNAs were ever validated for any of RNA1, 2, or 3 of CPsV. Reassortment between genome segments from different isolates may occur in plants infected with more than one isolate, as it has been shown for BIMaV.

The presence of one or more NLS reported for the RdRp protein (see below) suggests that replication may occur in the nucleus; however, gold immunolabeling and electron microscopy of RWMV-infected tissues showed accumulation of CP in the cytoplasm.

Properties and Functions of Gene Products

Two proteins are encoded in the viral complementary (vc) strand of *RNA1*, separated by an intergenic region of about 100 nt; the first of these is a protein of approximately 22–25 kDa. For CPsV and MLBVV this protein has been shown to function as viral suppressor of RNA silencing (VSR), and it is likely that the equivalent proteins of other ophioviruses have the same function; consistent with this function, a CPsV 24K:GFP fusion protein was found to accumulate in the nucleus and probably the nucleolus despite having an identified NES. Nucleolar import of CPsV 24K may be aided by an N-terminal proximal “GW” motif, while the BImaV 23K protein has an identified bipartite NLS not seen in the other ophioviruses for which the small protein from *RNA1* has been characterized. Indeed, the BImaV 23K has low identity to the equivalent proteins of CPsV, MLBVV, and LRNV. The CPsV 24K and MLBVV 25K proteins have both been demonstrated to bind long (114 bp) but not short (21 bp) dsRNAs, a property shared with their 54–55K MPs which have also been identified as VSRs (see below), and which also affect miRNA maturation.

The second, and major protein encoded by *RNA1* is the viral RdRp, which is of 261–280 kDa. The RdRp of each virus has the signature motifs present in RdRp of viruses of the order *Mononegavirales*, having a core polymerase module of about 240 aa residues which includes five conserved motifs; pre-motif A, plus motifs A to D. Of these, motif C is absolutely conserved between the five viruses for which the core polymerase sequence is available (CPsV, MLBVV, LRNV, RWMV, and BImaV), and includes the presumed RdRp active site “SDD” triad found in all negative strand RNA viruses with segmented genomes, including ophioviruses. In motif D, a Gly residue is conserved between MLBVV, LRNV, and RWMV, but is substituted by an Asp residue in CPsV and BImaV. The RdRps of CPsV, MLBVV, RWMV, and BImaV all have identified bipartite NLSs, with CPsV having dual NLSs, and the other viruses having only one, though no NLS has been reported for the RdRp of LRNV. In most viruses with a negative sense RNA genome, the RdRp is also incorporated in the virions, as in the absence of translation from the incoming genomic RNA, the RdRp is required to initiate infection. However, a variable proportion of positive (vc) strand RNA of ophioviruses is also encapsidated, which may overcome the necessity for other viruses with negative sense genomes to incorporate the RdRp into virions.

All of the characterized ophioviruses produce a protein of 50–58 kDa translated from the *RNA2* vc strand, initially identified as a movement protein belonging to the “30K superfamily” of MPs, and later shown to also include VSR activity. The MPs of CPsV and MLBVV interact with PD (presumably increasing its SEL, a characteristic of many different MPs), and with cellular microtubules, and also spread into adjacent cells. CPsV and MLBVV MPs interact with their homologous nucleocapsid protein (NP); interaction of MP with NP/coat protein is a common feature of MPs of other viral genera and families.

The predicted structures of ophiovirus MPs align with each other, and have a similar organization comprising a core domain, common to all MPs of the “30K superfamily”, including one α -helix, seven β -strands, and the conserved Aspartic acid (D) residue associated with increased SEL of PD and full MP function. The C-terminal domain has conserved secondary structure potentially involved in RNA binding and interactions with host proteins, and a conserved DTG tripeptide not observed in any other “30K superfamily” MPs. The 54K MP of CPsV is autocatalytically cleaved by an aspartic protease to generate an N-terminal 34K protein including the “30K core domain”, which forms tubules at PD to allow virus movement between cells, and a 20K product. The 20K includes the protease activity within the MP conserved C-terminal domain, with the absolutely conserved DTG tripeptide near the N-terminus of this domain; the cleavage site occurs about 30 residues upstream. The D residue is critical for cleavage; however, a high proportion of the CPsV 54K protein remains unprocessed even in native infections. Cleavage affects MP subcellular localization, and is required for efficient nuclear localization (presumably of the 20K cleavage product). Uncleaved 54K accumulated to a greater extent at chloroplasts, and although also observed at PD, no tubular structures were observed; whereas 34K expressed alone resulted in tubule production at PD. Chloroplast localization is presumably due to a predicted 21 aa residue N-terminal chloroplast transit peptide. The 34K cleavage product complements a movement-deficient TMV more efficiently than the full-length 54K, confirming movement function is due to the 34K. Both the 34K and 20K cleavage products form homodimers, consistent with 34K forming tubules, and the presumed dimeric catalytic triad for aspartic protease activity of the 20K product. Most viruses with tubule-forming MPs have isometric virions; it has been suggested that interaction between CPsV MP and NP may allow guidance of virions (or a ribonucleoprotein complex of viral RNA with both MP and NP) through tubules linking adjacent cells through PD. To date, only protease activity has been ascribed to the 20K cleavage product. Both (54K) MP and the *RNA1* 24K protein each have VSR activity, which is enhanced when the two proteins are co-expressed; each presumably functions at a different step of the RNAi pathway. As a 20K:GFP fusion protein traffics to the nucleus, the 20K cleavage product may have the VSR activity originally assigned to the 54K product.

It has been proposed that the CPsV 54K protein should be renamed “MP-PRO”, with the 30K cleavage product identified as “MP”, and the 20K cleavage product as “PRO”. This suggested nomenclature may be further modified if the VSR activity first associated with the uncleaved 54K protein is attributed to a specific cleavage product.

A minor protein of about 10 kDa is apparently encoded in the viral (v) strand of MLBVV *RNA2* and this would represent a unique case among the known ophiovirus genome structures, but its significance is still unclear.

RNA3 of all characterized ophioviruses encodes a single protein of 43–50 kDa, which is the viral nucleoprotein, alternatively described as the “coat protein” (CP) forming at least the bulk of the filamentous virions together with the genomic RNAs. The NP protein sizes of different ophioviruses ranges between 43 and 50 kDa (see [Table 2](#)), with FreSV NP of 48.4 kDa, and the sizes of RWMV (~43 kDa) and TMMMV (~47 kDa) NPs estimated by western blotting rather than from partial NP sequence data.

Ophiovirus NPs are relatively poor antigens. The antisera or, in one case, monoclonal antibodies, have been produced using purified virus preparations or recombinant protein. Western blots show that the NPs of RWMV, TMMMV, MLBVV, and LRNV are slightly to moderately related; CPsV NP appears to be unrelated to the others; no clear information is available for FreSV or BImaV. Genetic variability of the NP gene has been extensively studied in CPsV and MLBVV. Variability of the NP gene of CPsV was assessed serologically, and by sequence analysis of two regions located in the 3' and 5' halves of the gene. CPsV serological variability yielded 14 reaction patterns, without correlation between serogroups and specific aa sequences, field location, or citrus cultivar. Sequence analysis showed limited nucleotide diversity in the NP gene within the population, with diversity slightly higher in the 5' region. The ratio between non-synonymous and synonymous substitutions (dN/dS) for the two regions indicated a negative selective pressure for aa changes, with greater selection pressure at the 3' end. When the entire CP sequences were considered, two clusters were identified, one comprising 19 isolates from Italy and an isolate from Spain and a second one containing only the Florida CPsV isolate. Phylogenetic analysis of MLBVV NP genes has revealed two distinct clades, A and B, further divided into subclades A1 and A2, B1 and B2; however, this grouping was not correlated with symptom severity on lettuce or the geographic origin of the isolates, except that all Australian isolates fell into subclades A1 and A2; whereas European isolates were found in all four subclades, only European isolates fell into B1 and B2, including all reported isolates from *Sonchus* spp. in subclade B2. Whether these two clades or subclades show different characteristics with regard to virulence in indicator plants or serological relationships remains to be determined; as with CPsV, a low ratio of dN/dS was estimated for all MLBVV isolates and between the two subgroups, implying negative selection pressure for aa changes. A similar study of BImaV MP and NP sequences of isolates from British Columbia (Canada), Slovenia, and several regions within the United States found a low ratio of dN/dS for both genes. Under natural conditions, genetic stability of ophiovirus NPs seems to be the rule rather than the exception, perhaps due to the necessity both for structural integrity of the virions, and interaction with host or vector proteins.

The NP encapsidates both negative (v) and positive (vc) strands of the genomic RNA. Each NP includes a domain of almost 180 aa residues that is conserved among the NPs of viruses with negative strand ssRNA genomes, and is rich in α -helices. The NP of MLBVV and partial NP sequence of TMMMV share about 80% identity, showing the closest relationship between ophiovirus species; although distant serological relationships between MLBVV and TMMMV, and MLBVV and RWMV indicate the presence of some conserved epitopes between these viruses, no serological relationship was detected between these viruses and CPsV. CPsV and BImaV NPs share only 38% identity, despite their current status as the only ophioviruses infecting woody hosts.

A putative leucine zipper motif of six (CPsV) or four turns (MLBVV, TMMMV, FreSV, LRNV, and RWMV) followed by an SRCK tetrapeptide has been identified in the NPs of the six ophioviruses for which all or most of the NP sequence is available; for the complete NP of BImaV, a five turn leucine zipper motif followed by a TRCK tetrapeptide at the same spacing can be identified. Leucine zippers are associated with protein oligomerization and genome encapsidation, consistent with NP self-interaction and role of the NP in virion formation. Whether the SRCK/TRCK tetrapeptide may be involved in a specific interaction with zoospores of the various *Olpidium* spp. known to be vectors of most ophiovirus species remains to be determined.

An RNA4 has been identified only for MLBVV and LRNV; the 37 kDa proteins of MLBVV and LRNV share just over 40% identity, with a higher proportion of conserved residues in the N-terminal 60 aa residues than any other portion of the protein, suggesting that this is a functional domain; both the MLBVV and LRNV 37K proteins are predicted to have three trans-membrane domains, with the N-terminus 'outside', and the C-terminus "inside". Expression of the putative 10.6K frame-shift ORF present only in RNA4 of MLBVV has not been demonstrated. To date no function has been assigned to either of the ORFs encoded by RNA4.

Pathogenicity and Geographic Distribution

Psorosis is a graft-transmissible disease of citrus characterized primarily by bark scaling of the trunk and main branches of various *Citrus* species (Fig. 4). These symptoms were first reported from Florida and California, USA in the 1890s, and in the great majority of cases psorosis symptoms are associated with infection by CPsV. However, in a small proportion of trees with "psorosis-like" bark-scaling CPsV is not detected, and the idea of a non-CPsV psorosis-like disease of unknown etiology is emerging. In the past, different kinds of symptoms were described: "psorosis A" (PsA), characterized by causing bark-scaling in trunk and limbs of infected field trees, and staining of the wood; "psorosis B" (PsB), causing rampant scaling of thin branches in field trees and chlorotic blotches in old leaves with gummy pustules in the underside; "ringspot", characterized by presence of chlorotic blotches and rings in the old leaves of inoculated seedlings but apparently no specific symptoms on infected field trees or in other cases, chlorotic flecks and ringspots on leaves, and trunk and fruit symptoms. All these appear to be caused by CPsV. CPsV has been documented in many citrus production areas, including the USA, Argentina, Uruguay, Spain, Italy, Turkey, Lebanon, Egypt, Morocco, Tunisia, China, and Australia. The disease caused by CPsV has been brought under control in most advanced citrus-growing countries through implementation of rigorous indexing and quarantine. In Argentina it remains a severe problem, and it is still reported in the Mediterranean areas, while in citrus-growing parts of Asia the disease may well be widespread, although rigorous testing for the presence or absence of CPsV has generally been lacking. Among citrus types, sweet orange, grapefruit, and mandarin are most severely affected, whereas sour orange and lemon usually show foliar symptoms without obvious bark lesions. Infection with PsA isolates offers some cross-protection against the more severe symptoms induced by PsB isolates (also sometimes referred to as "Citrus ringspot" isolates). Disease severity is also affected by temperature, with cool temperatures increasing the probability of a shock reaction in the first growth flush following inoculation, whereas warmer temperatures may result in masking of foliar symptoms. Increased temperatures appear to allow greater RNA silencing by the host, resulting in lower viral accumulation.

Fig. 4 Bark scaling in citrus, typical of severe psorosis.

Lettuce big-vein disease was first reported in the United States in 1934 and occurs in all major lettuce producing areas in the world. The disease becomes more serious during cooler periods of the year. The main symptoms are vein-banding in the leaves, due to zones parallel to the vein cleared of chlorophyll (**Fig. 5**); there is associated leaf distortion, delayed head formation, and decreased head size. The causal agent of the disease, long known to be soil-transmitted, was first identified as "Lettuce big-vein virus" (LBVV) (genus *Varicosavirus*); more recently, re-evaluation of the etiology was necessary as a second less easily detected virus, MLBVV, was found in lettuces with big-vein symptoms. Following experimental inoculation of the two viruses together and separately, MLBVV was shown to be the etiological agent of big-vein, while LBVV, renamed as Lettuce big-vein associated virus (LBVaV), apparently plays no part in the disease, although it is almost always present, and is, like MLBVV, transmitted by *Olpidium*. Studies on symptom development in the field have confirmed that both viruses very commonly occur together in lettuce crops. MLBVV likely occurs worldwide; it is reported in California (USA), Brazil, Chile, France, Germany, Italy, Spain, the Netherlands, England, Denmark, Turkey, South Africa, Saudi Arabia, Japan, Australia, and New Zealand. To date, natural infection has been reported only in cultivars of *Lactuca sativa*, endive (*Cichorium endivia*), and two species of sowthistle (*Sonchus asper* and *S. oleraceus*).

LRNV is closely associated with lettuce ring necrosis disease, first described in the Netherlands and in Belgium as "kring necrosis" and also in France as "*maladie des taches orangées*", in the 1980s. It is an increasingly important disease of butterhead lettuce crops in Europe. Definitive proof that LRNV is the cause of ring necrosis is still awaited. In southern France the disease is observed primarily in winter lettuces (September–January) under plastic or glass, when the crop is maturing, the day length is short, and both light intensity and temperature are low. Symptoms depend on the lettuce type and environmental conditions, and mainly consist of necrotic rings and ring-like patterns on leaves, which may render the product unmarketable. LRNV is often found together with MLBVV (and, of course, LBVaV) with which it shares host and vector. The virus has also been reported in California.

Fig. 5 Leaf of butterhead lettuce showing big-vein symptoms. Close-up showing vein-banding.

Fig. 6 Shoot of blueberry infected with BIMA virus showing part of the range of symptoms often observed, which include chlorotic fleck and mottling, strong chlorotic mosaic, and combinations of yellow mosaic with areas of pink or orange coloration.

BIMA virus was initially described from an infected plant from Arkansas, USA, showing symptoms of mild to brilliant foliar mottle and mosaic (Fig. 6) observed since the 1950s in blueberry production areas across North America, Argentina, Chile, Europe, New Zealand, and South Africa. The disease is associated with late ripening, reduced yield, and poor quality fruit. Some leaves may turn partly or completely yellowish green, yellow, orange, or pink. BIMA virus has been specifically identified by molecular methods from several states in the USA, from British Columbia (Canada), Slovenia, Serbia, Turkey, and Japan, with the Slovenian isolates being most closely related to isolates from New Jersey, USA. Most of the Slovenian isolates were propagated from plants originally imported from New Jersey.

Necrotic disorders of freesia (*Freesia refracta* hyb., family Iridaceae), known as “leaf necrosis” and “severe leaf necrosis”, were first described in freesia crops in the Netherlands before 1970, and a similar disease, named “freesia streak”, was reported in England and Germany in the same years. The ‘severe leaf necrosis’ appeared to be caused by mixed infection with the potyvirus freesia mosaic virus and a virus with varicosavirus morphology and the same mode of transmission, that has been tentatively named freesia leaf necrosis virus. More recently in northwest Italy, a necrotic disease of freesia spread and caused considerable economic losses (Fig. 7), even though it was present since 1989. Both in Italy and in the Netherlands, the disease has been linked to the presence of an ophiovirus, named freesia sneak virus (FreSV). Typical symptoms are chlorotic inter-veinal spots and streaks at the leaf tips that expand downwards and turn necrotic, and may vary according to cultivar and climate. FreSV has since also been identified in freesia in England, Germany, the Netherlands, Bulgaria, New Zealand, Korea, Japan, and the USA, and from *Lachenalia* hybrids (family Asparagaceae) from South Africa.

RWMV was initially reported in two species, ranunculus (*Ranunculus asiaticus* hyb.) and anemone (*Anemone coronaria*) in northwest Italy since the 1990s. The pathogenic impact is uncertain as it was almost always found in mixed infection with other viruses commonly infecting the two species. The symptom description “white mottle” present in its name derives from the bright white mottling symptoms consistently observed on *Nicotiana benthamiana* leaves mechanically infected by RWMV. In some cases the bright mottle has also been observed in naturally infected ranunculus, always in mixed infection. Indexing for the presence of RWMV in ranunculus crops done in 1996 showed an incidence of 2.5% among symptomatic plants; furthermore, the very few plants apparently infected only with RWMV did not show any distinctive symptoms. Infection of ranunculus seedlings by mechanical inoculation results in limited necrosis and

Fig. 7 Symptoms of freesia necrotic disease on freesia leaves. Courtesy of D. Salvi, Studio Ferrari Salvi, Sanremo (IM) Italy.

Fig. 8 TMMMV symptoms on tulip (healthy tulip on the left). Courtesy of T. Morikawa, Toyama Agric. Res. Center, Tonami, Toyama, Japan.

deformation of stems and leaves; however, it is one of the most prevalent viruses in ranunculus crops in Italy, possibly as a result of establishment of the *Olpidium* vector in production fields. Infection of anemone was also typically in mixed infections, leaving the pathogenic potential of RWMV unclear. A report published by Horticulture Australia Ltd notes RWMV infecting pepper showing vein yellowing disease in Australia; the disease showing incidence up to 30% is widespread on the North Adelaide Plain but does not appear to cause significant yield loss or reduction in fruit quality. The symptoms are easily seen in young plants and fading as plants mature. More recently RWMV was detected in *Pittosporum tobira* in Italy, in mixed infection with Eggplant mottled dwarf rhabdovirus.

Tulip mild mottle mosaic disease, caused by TMMMV, is one of the most serious diseases in some bulb-producing areas of Japan (which produces bulbs on a large scale for the Southeast Asian market) and has been reported since 1979. Symptoms on tulips include color-attenuating mottle on flower buds and color-increasing streaks on petals ([Fig. 8](#)); mild chlorotic mottle and mosaic may appear along the leaf veins. TMMMV infection is apparently restricted to *Tulipa* species and cultivars, and has not been reported in other geographical areas.

Diagnosis

A pair of degenerate primers was originally designed from a conserved region of RNA1 (in the RdRp gene, located outside the sequence coding the polymerase domain). These primers, used in RT-PCR experiments, amplify a 136 bp DNA fragment from all recognized ophiovirus species and not from representative plant-infecting species of *Rhabdoviridae*, *Tenuivirus*, *Orthospovirus* and *Varicosavirus*. These genus-specific primers, by a simple RT-PCR assay, may lead to the detection of new ophioviruses, with the establishment, at least provisionally, of their taxonomic position, through phylogenetic analysis of the predicted 45 aa translation of the amplified fragment. When an ophiovirus infection is suspected, RT-PCR and qRT-PCR with specific primers are the most commonly used and sensitive method for specific diagnosis, both in plants and in the natural vector, even if ELISA using polyclonal antisera is still used for mass diagnosis. An RT-LAMP protocol was also developed for MLBVV; compared with DAS-ELISA and RT-PCR, RT-LAMP and IC-RT-LAMP (Immuno-Capture of particles) seem to have higher sensitivity (100-fold) but

similar specificity, with the advantage of a shorter assay time and no need for RNA extraction in IC-RT-LAMP. Recently NGS technology gained high importance in virus diagnosis, and the “small RNA-Seq” technique has been used to characterize the causal viruses of lettuce big vein disease, confirming the crucial involvement of MLBVV. NGS technology has a huge potential and may be easily used to find new hosts for ophiovirus species (as happened for the RWMV infection of *Pittosporum tobira*) and help to find new ones (as happened for the disclosure of blueberry infection by BLMaV, the most recently recognized official ophiovirus).

Transmission, Experimental Host-Range and Control

Most ophiovirus infections in nature are recognized as soil-borne. The natural vector of most ophiovirus species has been identified as *Olpidium* spp., ubiquitous obligate root-infecting fungal parasites (*Chytridiomycota*, chytrids) with cosmopolitan distribution. At least two species, *O. brassicae* and *O. virulentus* seem to be involved in ophiovirus transmission. Studies on MLBVV and *O. virulentus* suggest that the virus is carried internally (*in vivo*) in zoospores and resting sporangia. Virus-free zoospores acquire the virus during the vegetative part of their life cycle in the roots of virus-infected host plants. Zoospores released from infected sporangia carry the virus internally in their protoplasts and transmit it to healthy roots. *In vivo* acquisition is also supported given that resting spores can remain viruliferous in soil for decades in the absence of a growing host plant. The mechanism by which MLBVV and likely other ophioviruses are acquired and released into plant hosts by *Olpidium* is unknown; the possibility of ophioviruses multiplying in the fungal vector has not been reported to date. *Olpidium* spp. transmission has been proved for TMMMV, MLBVV (*O. virulentus*), LRNV, FreSV (*O. brassicae*) and BLMaV (*O. virulentus*). No information on natural vectors is available for RWMV but soil transmission is likely. CPsV is commonly transmitted by vegetative propagation and no natural vectors have been so far identified; in some cases natural tree-to-tree spread of psorosis in limited citrus areas has been reported, but the spatial patterns would suggest a hypothetical aerial vector instead of a soil-borne one. However, CPsV has been detected in the roots of infected grapefruit trees, and in zoospores of an unidentified *Olpidium*-like fungus released from sporangia in infected roots, but not from healthy controls.

The thick cell-walled nature of *Olpidium* spp. resting spores and their persistence in the soil for greater than 20 years makes ophiovirus-transmitted disease control most challenging, especially after the banning (Montreal Protocol) of use of chemicals for soil sterilization due to deleterious effects on the environment. Environmentally more sensitive control methods can be applied in order to reduce the spread and severity of the diseases. For nurseries, for example, disinfection of soil and potting mix, surface sterilization of seed, and the use of filtered/UV-treated water and nutrients, and clean production areas may all be important in the management of MLBVV and LRNV in lettuce. Crop covers, which affect the favorable environmental conditions for the viruses by lowering soil temperature and raising air temperature, were also shown to reduce the disease symptoms in lettuce. Moreover, the use of resistant or tolerant crops may be a good choice. In Japan, the use of resistant tulip cultivars is the most important component of managing TMMMV disease, as it can be highly effective and has no deleterious effect on the environment; resistance assays have allowed researchers to identify highly resistant tulip lines and use them for breeding new resistant cultivars. In the case of CPsV, control of the sanitary status of mother plants for producing propagating material is essential. Shoot-tip grafting *in vitro* associated with thermotherapy or somatic embryogenesis from stigma and style cultures have been successfully used to eliminate CPsV from plant propagating material. Preliminary results of a shoot apical meristem culture procedure performed on RWMV-infected ranunculus was also successfully used for ophiovirus eradication: the use of seeds and *in vitro* virus eradication can also be applied to currently vegetatively propagated ornamentals like freesia, ranunculus and anemone, to control ophiovirus infection. Genetic engineering of citrus and lettuce in recent years has shown promising results for obtaining ophiovirus resistance; several pineapple sweet orange plant lines transformed with a hairpin construct derived from the CPsV nucleoprotein gene showed varying responses from tolerance to full resistance traits toward both psorosis variants, a strategy that seems promising for a biotech product aimed at eradicating psorosis. Stable, marker-free and MLBVV-resistant lettuce lines were also engineered, in which MLBVV nucleoprotein gene is controlled by plant regulators; the new lines can be used as resistant cultivars or parental source for breeding.

All of the characterized ophioviruses are mechanically transmissible to a limited range of test plants, including Chenopodiaceae and Solanaceae, inducing local lesions; in some cases systemic mottle or apical leaf deformation and necrosis can occur. Systemically infected test plants can, in many instances, be advantageous for virus characterization, because of the enhanced virus multiplication and the possibility to obtain a high amount of purified virus. Chilling of source tissue, buffers, and equipment, together with additives such as antioxidants, enhance mechanical transmission of most, if not all ophioviruses. *Nicotiana benthamiana*, *N. clevelandii*, *N. occidentalis*, and *Chenopodium quinoa* are among the bioassay plants most often reported to be susceptible (Table 3). However, mechanical transmission is often difficult, and serial transfer between test plants is not always successful; there are also differences in ability or efficiency of mechanical transmission between isolates of CPsV. Transmission by the natural vectors, *Olpidium* spp. (*O. brassicae*, *O. virulentus*, or *O. bornovanus*) has rarely been used for host range tests, while dodder (*Cuscuta* spp.) has been demonstrated to transmit CPsV between citrus types.

CPsV is efficiently transmitted to susceptible citrus or citrus-related species by grafting, infecting *Microcitrus inodora* and *Fortunella hindsii* symptomlessly but with high ELISA values; other citrus relatives (*Citrus depressa*, Carrizo citrange, *Eremocitrus glauca*, *Microcitrus virgata*, and *Clausena excavata*) produced a severe shock reaction in the first flush of leaves, but did not flush again. Symptom intensity of some susceptible hosts (typically chlorotic flecking in young leaves) is correlated with virus accumulation as measured by ELISA, but mild symptoms were observed in Cleopatra mandarin, sour orange (*C. aurantium* L.), and citrumelo (*C. paradisi* × *Poncirus trifoliata*), which were negative by ELISA. Mechanical inoculation to test plants is also achieved.

MLBVV is reported to be more readily mechanically-transmissible than LBVaV, with which it is commonly found in mixed infection in lettuce; serial transfers from an initial mixed infection have resulted in recovery of only MLBVV after the third transfer to either lettuce or *N. benthamiana*. Continued mechanical transfers may result in loss of transmission by *O. brassicae*, and loss of

Table 3 Symptomatology on test plants commonly used for ophiovirus biological assays

– no information available.

ability to cause big vein symptoms in lettuce. Mechanical transmission of LRNV to test plants has been reported, with the most evident systemic symptoms in *N. occidentalis* and *N. hesperis*.

BlMaV is the most recently identified ophiovirus, and to date there are no reports of mechanical transmission, and no host range data are available, beyond blueberry infection. Transmission assays using blueberry seedlings and BlMaV-infected *Olpidium virulentus* were positive.

RWMV is able to infect several test plants; the inoculum source can maintain infectivity only if stored in liquid nitrogen. Local lesions are observed also in *C. capitatum*, *C. murale*, *C. album*, and local infection is also detected in *Spinacia oleracea* and *Vigna unguiculata*. Ranunculus seedlings (*Ranunculus sardous* and *Ranunculus* hybrid) challenged by mechanical inoculation with RWMV became infected, showing local and systemic necrosis.

FreSV can be transmitted to test plants; in some cases serial passage on *N. occidentalis* may yield evident chlorotic mosaic. Mechanical inoculation of purified FreSV to healthy freesia seedlings was never successful, however, freesia seedlings challenged by FreSV-infected *O. brassicae* resting spores became positive for FreSV infection.

Transmission of TMMMV to common test plants and to *Tetragonia expansa*, *Sonchus oleracea*, and *Beta vulgaris* resulted in only local infection.

Cytopathology

Thin sections of *Nicotiana clevelandii* leaves mechanically infected by RWMV have been examined by electron microscopy, but no distinctive inclusions were observed and no virus particles were seen. In classical thin sections, viral nucleic acids stain well but protein coats show low contrast, so it is not surprising that very thin nucleoprotein threads in random orientations should escape detection. After gold immune labeling with RWMV-specific polyclonal antibodies, sections of the cytoplasm of parenchyma cells were seen in the EM to be clearly labeled, but nuclei, chloroplasts, mitochondria, and microbodies were unlabeled. Confocal observation for subcellular localization of CPsV and MLBVV coat proteins linked to the fluorescent GFP molecule show cytoplasmic localization.

Ultrastructural changes have been reported in leaves of grapefruit infected with CPsV, but apparently free of Citrus tristeza virus (CTV) and Citrus exocortis viroid (CEVd), resulting in decreased thickness of both the phloem and the xylem, including reduced vessel diameter. Fewer oil glands, of smaller diameter than normal were observed, together with many abnormal chloroplasts with disorganized grana stacks and thylakoid membrane. Crystal idioblasts (cells containing calcium oxalate crystals) were found to be lacking in the palisade layer below the upper epidermis, in contrast to leaves of healthy plants, while inclusion bodies and tubular multi-membrane bodies were also observed. Although negative for CTV and CEVd, these plants may have been infected with other viruses, and some of the effects reported may result from reduced auxin levels rather than a direct presence of viral components.

Concluding Remarks

Ophioviruses are probably more widespread than currently known and they apparently have a very long evolutionary history. Psorosis of *Citrus* spp. and big-vein disease of lettuce, together with the necrotic disease of freesia and the blueberry syndrome, are relevant in agricultural production. Crop protection against ophiovirus infection is prevention centered; for this reason, there is a

need for resistance genes to be identified, or for introduction of resistance through biotechnological methods, together with application of good agricultural practices.

Glossary

Ambisense genome Viral RNA genome with open reading frames in both the viral- and viral complementary (vc) sense on the same genome segment.

Envelope Membrane-like structure that packages genome segments.

Intergenic region It is the untranslated, A-U rich region found between the two open reading frames on the S and M RNA segments.

Negative sense genome Viral RNA genome that codes for

proteins in the vc sense. Transcription of vc mRNA is required for translation of viral proteins.

Nucleocapsid Viral RNA encapsidated by nucleoproteins.

Protoplast Plant cell lacking its cell wall.

Ribonucleoprotein complex Consisting of the viral RNA genome segment, nucleoprotein, and a small number of polymerase molecules.

Virion Quasispherical structure containing the viral genome and bounded by a membrane-like envelope.

History

Diseases now known to be caused by Tomato spotted wilt virus (TSWV) were first reported in 1915 and were shown to be of viral etiology by 1930. This taxon of plant viruses was categorized as a monotypic virus group consisting of a single virus (TSWV) until the report of impatiens necrotic spot virus (INSV) in 1991. Thus, most of the characteristics which define the genus *Orthotospovirus* were obtained through investigation of TSWV even after the discovery of additional viruses in the genus (Table 1). Biological investigations beginning in the 1940s revealed a virus that had an unusually large host range and occurred in nature as a complex mixture of phenotypic isolates. However, it was one of the least stable viruses and most difficult plant viruses to mechanically transmit. Although the enveloped virions were observed in the 1960s, molecular characterization and elucidation of the genome organization were not completed until the early 1990s. The virus was shown to be vectored by thrips in the 1930s and later transmitted in a persistent manner. Thrips were demonstrated to be a host for replication of the virus and that replication was required for transmission in the early 1990s. Later, it was recognized that limited, localized replication may occur in thrips that does not result in the thrips becoming viruliferous. Advances in gene function and cellular biology have been limited due to the absence of a robust *in vitro* plant or thrips cell culture system, and lack of an efficient reverse genetics system. However, limited progress has been made utilizing gene expression systems and classical viral genetics.

^aTentative orthotospoviruses that have been described and proposed to the International Committee on Taxonomy of Viruses (ICTV) and waiting for the final approval as definitive species.

Note: Updated table from Rotenberg, D., Jacobson, A.L., Schneeweis, D.J., Whitfield, A.E., 2015. Thrips transmission of tospoviruses. *Current Opinion in Virology* 15, 80–89. doi:10.1016/j.coviro.2015.08.003.

Taxonomy and Classification

In addition to the genus *Tenuivirus* (family *Phenuiviridae*), the genus *Orthotospovirus* (family *Tospoviridae*) encompasses the plant-infecting viruses of the order *Bunyavirales*. All these plant viruses share many molecular characteristics with animal-infecting viruses classified in this order. The orthotospoviruses, for example, have an enveloped virion containing the viral genome which is distributed among three RNA segments that replicate in a manner consistent with that of other vertebrate-infecting bunyaviruses such as hantaviruses, phleboviruses, orthobunyaviruses, etc. All three RNA segments have highly conserved, complementary termini resulting in a pan-handle structure and genes with similar functions. Differently, the small (S) and medium (M) segments of orthotospoviruses encode two genes in opposite or ambisense polarity.

Classification of an orthotospovirus population as a distinct viral species is based upon the similarity of sequence between the nucleocapsid genes of the respective viruses (Fig. 1). This is in contrast to the system used to differentiate animal viruses in other genera which traditionally relied on serological neutralization of infectivity or other biological properties (hemagglutination)

Fig. 1 Phylogeny of the complete S-RNA genome segment sequences of orthotospoviruses belonging to recognized and proposed species within the genus *Orthotospovirus* in the family *Tospoviridae*. The midpoint-rooted tree was deduced in MEGA X v. 10.0.5 after alignment in Muscle, using the neighbor-joining method based on the maximum composite likelihood substitution model with uniform rates and 1000 bootstrap replications. The scale bar indicates the number of substitutions per site. Bootstrap support for branches is shown at the junctions of branches where it was >50%. Accession numbers are given in Table 1.

mediated by the glycoproteins. Orthospovirus isolates with greater than 90% nt similarity in the nucleocapsid gene are classified as isolates of the same viral species.

Geographic Distribution

TSWV, the type species member of the orthospoviruses is found worldwide in association with its thrips vector. The wide host-range of TSWV and its thrips vectors is consistent with the geographic distribution. Other orthospoviruses have more well-defined distribution (**Fig. 1**). For example, Groundnut bud necrosis virus (GBNV), Watermelon bud necrosis virus (WBNV), and Watermelon silver mottle virus (WSMoV), that are transmitted by *Thrips palmi*, a thrips species found only in the subtropics and only known to occur in South-East Asia. Another anomaly is INSV. While INSV is reported to occur around the world, it is almost entirely limited to greenhouse-grown floral crops.

Host-Range and Virus Propagation

TSWV has one of the most diverse host-ranges of any plant-infecting virus. This virus infects over 900 plant species belonging to 90 botanical families, both monocots and dicots. In addition, TSWV is reported to be transmitted by at least nine thrips species. Important economic plants susceptible to TSWV include tomato, potato, tobacco, peanut, pepper, lettuce, papaya, and chrysanthemum. Other orthospoviruses (e.g., IYSV) have much narrower host-ranges and thus the broad host-range of TSWV is not characteristic of the genus. These viruses can be transmitted mechanically or by their thrips vectors. Recently, it has been shown that Soybean vein necrosis virus (SVNV) can be seed-transmitted at a rate of 6% in soybean plants, but this phenomenon has not been observed for any other orthospovirus. RNA preparations are not infectious. There are no robust cell culture systems for orthospoviruses. However, plant protoplasts and insect cells have been successfully inoculated.

Virion Properties

Orthospovirus virions are quasispherical, enveloped particles with 80 – 120 nm in diameter (**Fig. 2**). Two viral coded glycoproteins, GN and GC, are embedded in the viral envelope and form 5–10 nm surface projections. Ribonucleoprotein (RNP) particles consisting of the viral RNA encapsidated by nucleoproteins (ribonucleocapsid), and a small number of polymerase molecules are contained within the envelope. Ribonucleocapsids are pseudocircular due to noncovalent bonding of the complementary RNA termini. Intact

Fig. 2 *Orthospovirus* quasispherical virion particles. Left. Electron micrograph of negatively stained particles of Tomato spotted wilt virus (TSWV). The bar represents 100 nm. Courtesy of J. van Lent. Right. The S, M, and L RNA genomic segments are encapsidated by nucleoproteins, which are in association with L protein (polymerase) molecules, and form pan-handle structures due to the complementarity of their 5'- and 3'-ends. The glycoproteins GN and GC are embedded within the viral envelope.

virions as well as carefully prepared RNPs retrieved from sucrose or CsSO₄ gradients are infectious. There are several reports that TSWV and INSV isolates, while infectious, are defective for virion formation.

Genome Properties

Orthospoviruses have a single-stranded, tripartite RNA genome with segments designated as L, M, and S in order of decreasing size (Fig. 3). The termini of each of the RNA segments consist of an eight nt sequence (5'-AGAGCAAU-3') that is strictly conserved among all orthospoviruses. The remaining untranslated region at the termini also has a high degree of complementarity. Base pairing at the termini between the inverted complementary sequences supports a pan-handle structure that most likely serves as a promoter for replication. For TSWV, the L RNA has 8.9 nt and codes for the L or RNA-dependent RNA polymerase (RdRp) protein in the viral complementary (vc) sense (Fig. 3). The M and S RNAs are in ambisense orientation. The M RNA has 4.8 nt and codes in the viral sense for the non-structural protein NSm and for the GN/GC precursor glycoprotein in the vc sense. The S RNA presents 2.9 nt and codes in the viral sense for the nonstructural protein NSs and the nucleocapsid (N) protein in the vc sense (Fig. 3).

Intergenic regions (IGRs) of TSWV M and S RNA have variable lengths, are A–U rich, and are the most hypervariable regions of the genome. The 5'- and 3'-ends of the IGRs are conserved, separated by variable sequences, deletions, and insertions. In addition, highly conserved sequences are embedded within the S RNA IGR. A 33 nt duplication occurring in the S RNA IGR of some isolates has been correlated with loss of competitiveness in mixed infections of isolates with and without the duplication. A 31 nt conserved sequence, with significantly higher GC-content compared to the remaining S RNA IGR, has also been found in some TSWV isolates. The IGRs of the M and S segments have high inclination for base pairing thought to be involved in initiation and termination of transcription.

Fig. 3 *Orthospovirus ambisense* genome organization (inset in figure) and expression strategy. Positive (+) and negative (–) sense ORFs are dark and light shaded tubes, respectively. Proteins from the S and M segments are translated from subgenomic mRNAs which are capped with 10–20 nt of host-derived RNA at the 5'-end.

There is speculation that the termination of transcription is dictated by a conserved nt sequence (CAACUUUGG) in the center of the S and M RNA IGR or that it is due to a secondary structure highly stabilized in the 31 nt region referred to above.

Full length molecules of the M and S RNAs are found in infected tissue and purified virions in both the viral and vc sense (approximate ratio of 10:1), consistent with ambisense segments from other viruses. Defective interfering RNAs (DIs) associated with attenuated symptom expression and increased replication rate are also frequently observed. DIs from the L ORF in TSWV infected tissue are the result of and associated with attenuated infectivity. Deletions, frameshift, and nonsense mutations in the GN/GC ORF have been shown to interfere with thrips transmissibility and virion assembly. Frameshift and nonsense mutations with unknown effect have also been identified in the N ORF. The formation of DIs is favored by repeated mechanical passage in certain plant hosts, high inoculum concentration, and low temperatures. Available evidence supports the hypothesis that secondary structure rather than the RNA sequence itself is the primary determinant of the site of deletion. There is also a high frequency of DIs that maintain the original reading frame resulting in translation of truncated proteins whose existence was confirmed in nucleocapsid preparations.

Protein Properties

The 330–336 kDa L protein encoded by the L RNA has been identified as a RdRp through sequence homology with other members of the order *Bunyavirales* and identification of sequence motifs characteristic of polymerases. RdRp activity has been associated with detergent-disrupted TSWV virion preparations.

The 34 kDa NSm protein encoded by the M RNA has been shown to induce tubule structures in plant protoplasts and insect (*Spodoptera* and *Trichoplusia*) cells. Induction of tubules in plants, ability to change the size exclusion limit of plasmodesmata, an early expression profile and complementation of cell-to-cell and systemic movement in a movement-defective Tobacco mosaic virus vector is evidence that NSm is the TSWV movement protein and that it supports long-distance movement of viral RNAs. In thrips, NSm does not aggregate into tubules, indicating that this protein might not have cell-to-cell movement function in the vector's life cycle. It is also known that NSm specifically interacts with the N protein, the At-4/1 intra- and intercellular trafficking plant protein and binds single-stranded RNA in a sequence-nonspecific manner. An NSm homolog is absent in the vertebrate-infecting viruses of the order *Bunyavirales*. The 127 kDa GN/GC precursor glycoprotein also coded by the M RNA contains a signal sequence that allows its translation on the endoplasmic reticulum. Proteolytic cleavage of the polyprotein does not require other viral proteins. The molecular mass of GN and GC is 78 kDa and 54 kDa, respectively, for TSWV. Evidence for the involvement of the glycoproteins in thrips transmission is provided by: (1) their interaction with proteins of the thrips vector, (2) their association with the insect midgut during acquisition, (3) the loss of thrips transmissibility of envelope-deficient mutants, (4) the presence of a glycoprotein sequence motif that is characteristic for cellular attachment domains, and (5) the observation that only reassortants with the M RNA of a thrips-transmissible isolate rescue thrips transmissibility. Specifically, GN is involved in virus binding and/or entry in thrips midgut cells, whereas GC is a possible fusion protein playing a significant role in pH-dependent virus entry. It is also believed that these proteins are implicated in virion assembly.

The NSs protein encoded on the S RNA is 52 kDa and accumulates to high levels as loose aggregates or paracrystalline arrays of filaments. NSs has RNA silencing suppressor activity, affects symptom expression in TSWV-infected plants, and is not present in the mature virus particle. The N protein, also encoded by the S RNA, ranges in size from 28.1 to 30.9 kDa depending on the virus. This protein encapsidates the viral RNA segments, is highly abundant, and is the predominant protein detected in serological assays. A 'head-to-tail' interaction of the nucleoprotein N terminus (aa 1–39) with the C terminus (aa 233–248) results in multimerization.

Replication

Replication of viral RNA and assembly of virions occurs in the cytoplasm of both plant and insect cells. Orthotospovirus replication, however, has mainly been described based on plant infection. Upon entry into the plant cell, the virus loses its membrane and releases infectious nucleocapsids into the cytoplasm. In thrips cells, infection by orthotospoviruses is accommodated by binding of the viral surface glycoproteins to a host cell receptor(s) (possibly a 50 kDa and/or a 94 kDa protein). This is followed by release of infectious nucleocapsids into the cytoplasm, through fusion between the viral and thrips membranes possibly initiated by low pH. Depending on the concentration of N protein, the viral RNA is either transcribed or replicated. At low N concentrations, the polymerase transcribes mRNAs that are translated into the virus proteins. Translation of proteins from the S and M ambisense RNAs occurs from subgenomic mRNAs (Fig. 3). The S and M subgenomic mRNAs are capped at the 5' terminus with 10–20 nt of non-viral origin indicating that orthotospoviruses utilize a cap-snatching mechanism to regulate transcription. Leader sequences of Alfalfa mosaic virus have also been detected as caps of TSWV mRNA in mixed infections of the two viruses. The TSWV transcriptase has a reported preference for caps with multiple base complementarity with the viral template. Upon increase of N protein concentration, the polymerase switches its mode to replication with the viral RNA serving as the template. Replicated viral RNAs form RNPs that can presumably associate with the NSm protein for movement through plasmodesmata to adjacent plant cells through tubular structures. Alternatively, RNPs form new virions by associating with the glycoproteins and budding through the Golgi membranes. Virions are initially double-membraned, but soon coalesce and form groups of virions with a single membrane surrounded by another membrane.

Pathogenicity and Cytopathology

Orthotospoviruses are noted for the severity of the diseases they cause in plants. Symptoms are highly variable, depending on the virus, the virus isolate, the host plant, time of the year, and environment, and are thus of little diagnostic value. Chlorosis, necrosis, ring or line patterns, mottling, silvering, and stunting often appear on inoculated and systemically infected leaves. Systemic invasion of plants is frequently nonuniform. Stems and petioles may exhibit necrotic lesions. Observed symptoms often mimic disease and injury caused by other biotic and abiotic stresses. Infection of younger plants results in severe stunting and high mortality rates. TSWV has been shown to affect more severely *Datura*, *Nicotiana*, and *Physalis* plants under a specific temperature regime (daytime, $29 \pm 2^\circ\text{C}$, nighttime, $24 \pm 3^\circ\text{C}$). The effect of orthotospovirus infection on thrips has been controversial, due to the confounded effects of plant host, virus, and environment on the insect vector and the genetic variability of thrips and virus populations. TSWV infection of *F. occidentalis* provided evidence that thrips exhibit an immune response to the virus. Recent work with TSWV-infected *F. fusca* reared on infected foliage indicated a direct effect of the virus on thrips resulting in reduced fitness. The same study showed that the plant infection status and the TSWV isolate have also an effect on the insect, explaining the variable results obtained from independent studies of virus pathogenicity on the insect vector.

Orthotospoviruses induce characteristic cytopathic structures that are host and virus-isolate dependent. In addition to virions, inclusions of viroplasms consisting of the NSs or N protein may be abundant in the cytoplasm. NSs may aggregate in loose bundles (e.g., TSWV) or in highly ordered paracrystalline arrays (e.g., INSV). Excess N protein occurs in granular electron dense masses. NSs and nucleocapsid protein inclusions have been observed in infected plant and insect cells. NSm protein induces tubule structures in plant protoplasts and insect cells.

Transmission and Epidemiology

Orthotospoviruses are transmitted from plant to plant by at least sixteen thrips species in the genera *Ceratothripoides*, *Dictyothrips*, *Frankliniella*, *Neohydatothrips*, *Scirtothrips*, and *Thrips*. Among the more common vectors are *Frankliniella occidentalis*, *F. fusca*, *F. schultzei*, *F. intonsa*, *F. bispinosa*, *Thrips palmi*, *T. setosus*, and *T. tabaci*. Thrips feed on the cytoplasm of plant cells. The contents of infected cells are ingested and the virus is transported along the lumen of the digestive tract to the midgut, the primary binding and entry site into the insect cells. The brush border of the midgut lumen is the first membrane barrier that the virus encounters. The virus replicates in the midgut and crosses the basement membrane into the visceral muscle cells. The virus subsequently enters the primary salivary glands. It has been hypothesized that the virus moves from the midgut to the salivary glands through infection of ligament-like structures, or when there is direct contact between membranes of the visceral muscles and the primary salivary glands during the larval stages of development. A less plausible hypothesis is that the virus infects the salivary glands after entry and circulation in the hemocoel. Viral inoculum is introduced into plants in the insect saliva coincident with feeding on the plant by adult thrips.

The process of successful acquisition occurs only by larvae and acquisition rates decrease as larvae develop, affecting adult vector competency. Vector competency is also determined by the thrips' feeding preference on a particular host, the uniformity of distribution of virus in plant cells, the rate of virus replication in the midgut, and the extent of virus migration from the midgut to the visceral muscle cells and the salivary glands. In some instances the virus can be acquired by adult thrips and infects midgut cells, but is unable to spread further possibly due to the formation of an age-dependent midgut barrier (e.g., basal lamina). Research has shown the existence of thrips transmitters with detectable levels of virus, nontransmitters with detectable virus, and nontransmitters with no detectable virus, supporting multiple sites for vector specificity between orthotospoviruses and thrips. Evidence for replication of the virus in the insect vector is based on the accumulation of NSs and the visualization of viral inclusions in midgut epithelial cells, muscle cells, and the salivary glands. Although the virus is maintained transtadially throughout the life of the insect, there is no evidence for transovarial transmission. Thus, each generation of thrips must acquire the virus during the larval stages.

The primary dispersal of orthotospoviruses is by adult thrips and dissemination of infected somatic tissue in vegetatively propagated crops. These viruses are thought to move long distances in thrips carried by wind currents. They may also survive in commercial agricultural systems in weeds that serve as a bridge between crops. Infected summer weeds (e.g., in NC *I. purpurea*, *I. hederacea*, *M. verticillata*, *A. palmeri*, *C. obtusifolia*, *R. scabra*, *Ambrosia artemisiifolia* L., *Polygonum pennsylvanicum* L., and *Chenopodium album* L.) are the principal source for spread of TSWV to winter annual weeds, from which the virus is spread to susceptible crops in spring. Secondary spread within a crop can only occur in crops that concomitantly support virus infection and reproduction of the vector as only the larval stage can acquire the virus for transmission. Transmission through plant seed has only been demonstrated for SVN but at a low rate. The emergence of these viruses as serious pathogens in crops has been attributed to the increased prevalence of *F. occidentalis* as an agricultural pest on a worldwide basis.

Genetics and Evolution

The knowledge base for genetics and evolution of orthotospoviruses has been derived almost exclusively from TSWV. TSWV has a characteristic ability to adapt to new or resistant hosts and to lose phenotypic characters following repeated passages in experimental

hosts, especially *Nicotiana benthamiana*. The virus occurs in plants as a heterogeneous mutant population with one or two predominant haplotypes and 9–21 rare haplotypes. Recent research shows that natural TSWV variants evolve in nature through recombination, random genetic drift, and mutation. Inter-genomic recombination is important for the genesis and evolution of ancestral TSWV lineages. Genetic drift during thrips transmission and mutation concurrent with virus population growth, shape the genetic architecture of the most recently evolved lineages. The existence of single viral strains as mutant populations and recombination in ancestral viral lineages arm TSWV with a unique genetic reservoir for causing disease and spreading in epidemic proportions in nature. Additional research at the species level supports a distinct TSWV geographical structure and the occurrence of species-wide population expansions. TSWV is also known to use reassortment of genome segments to adapt to resistant hosts under specific laboratory conditions. The determinants of adaptation to resistance in tomato and pepper have been mapped to the M and S RNAs, respectively. Tomato chlorotic spot virus (TCSV) and Groundnut ringspot virus (GRSV) share the same M segment due to host adaptation reasons. Phylogenetic analyses suggest that TCSV putatively incorporated this genomic segment from GRSV upon a reassortment event since the parental genotype of TCSV remains unknown. Little is known about the thrips–orthospovirus coevolution and the genetic diversity of the thrips vector itself. The altered status of *Thrips tabaci* as a TSWV vector is one of the very few likely examples of coevolution between orthospoviruses and their insect vector.

Detection and Diagnosis

Orthospoviruses have certain unique biological properties that are useful for diagnosis. These viruses can be mechanically transmitted by gently rubbing inoculum on plants dusted with carborundum. *Nicotiana glutinosa* L., *Chenopodium quinoa* Wild., and garden petunia give characteristic lesions that progress as spots or concentric zones, and sometimes as lethal necrosis. Orthospoviruses can also be identified by electron microscopy of leaf-dip preparations on thin sections of infected plants. Additional techniques for identification are based on the enzyme-linked immunosorbent assay (ELISA) using polyclonal and monoclonal antibodies, and detection of viral-specific nucleic acids using ribo- and cDNA-probes. The reverse transcription-polymerase chain reaction (RT-PCR) is the most powerful and commonly used technique for detecting small amounts of orthospovirus RNA. Real time RT-PCR has been successfully used to detect and quantify TSWV in leaf soak and total RNA extracts from infected plants and thrips. RT-PCR with degenerate primers can detect five distinct orthospovirus species. Tissue selection and sampling strategy are critical factors in TSWV diagnosis and detection regardless of the technique. Because, TSWV titer varies throughout the plant and does not spread uniformly throughout plants that are ‘systemic’ hosts, sampling strategies should be validated in each situation. Nowadays, with the availability of high-throughput sequencing techniques, also referred to as next-generation sequencing (NGS), viruses have been identified and had their genomes completely sequenced following a fast and unbiased manner. Thus, reports of new viruses include the genetic characterization of entire genomes, which facilitates evolutionary and biological studies.

Prevention and Control

Orthospoviruses cause significant economic losses annually, due to suppressed growth, yield, and reduced quality. These viruses can be partially managed in well-defined cropping systems such as glasshouses by obtaining uninfected plant propagules, implementing a preventative thrips control program in high risk areas, together with constant monitoring of production areas for thrips and infected plants. However, these strategies are costly and require intensive management. Control in field crops is problematic due to the array of external sources of inoculum. Vector control is generally ineffective against the introduction of virus from external sources, due to thrips’ high fecundity, ability to develop insecticide resistance, and to infest many TSWV-susceptible crops. Some measure of control can be achieved using thrips-proof mesh tunnels in the field and reflective mulches. Cultural practices such as utilization of virus-tested planting stock, careful selection of planting dates, removal of cull piles and weeds, rotation with nonsusceptible crops, prevention of planting TSWV-susceptible crops adjacent to each other, reduced in-field cultivation to avoid movement of thrips from infected sources, can reduce the spread of orthospoviruses. In peanuts, higher plant density, planting from early until late May and application of selected insecticides have reduced the incidence of TSWV. In flue-cured tobacco, early-season treatment with activators of plant defenses and insecticides have also significantly reduced TSWV incidence.

Deployment of resistant cultivars has provided benefits in few crops infected by orthospoviruses. Single-gene resistance is available for orthospovirus in a limited number of tomato (*Sw-5b*) and pepper (*Tsw*) cultivars. Naturally occurring, resistance-breaking isolates of TSWV have been recovered from pepper and tomato cultivars containing their respective resistance genes. Nevertheless, a correct management of *Sw-5b*-resistant cultivars has shown that this resistance can be durable. The main strategy is to decrease the selection pressure on virus populations by alternating resistant and susceptible cultivars or by planting susceptible tomatoes alongside production fields. The *Sw-5b* protein is a Nucleotide-Binding site and Leucine-Rich Repeat (NB-LRR) receptor with nucleocytoplasmic distribution that confers a dominant, high-spectrum resistance against isolates of Alstroemeria necrotic streak virus (ANSV), Chrysanthemum stem necrosis virus (CSNV), GRSV, INSV, TCSV, and TSWV. The *Sw-5b* protein activates resistance by direct recognition of orthospovirus NSm proteins. Co-dominant markers have been developed for screening *Sw-5b*-containing tomato cultivars. Co-dominant cleaved amplified polymorphic sequence (CAPS) marker has also been developed for TSWV marker-assisted selection in pepper. ‘Field’ resistance has been reported for some peanut varieties. Progress has been made in

understanding the genetic basis of the ability of TSWV to overcome single gene resistance by mapping determinants to specific segments of the TSWV genome and characterizing the selection process. Pathogen-derived resistance utilizing the N and NSm genes has been effective in some greenhouse and field tests; however, isolates have been obtained that overcome nucleocapsid mediated resistance. Best suppression of TSWV epidemics has been achieved with the integrated use of resistant cultivars, chemical, and cultural practices.

Future Perspectives

The last few years have been characterized by exciting developments in our understanding of orthotospovirus molecular biology, diversity, evolution, and virus–host relationships. Within this context, several new viruses and thrips vectors have been reported. Advances have also been made in understanding orthotospovirus resistance mechanisms in plants, especially concerning *Sw-5* resistance genes, which have brought some insights in the management of orthotospovirus in the field. Unfortunately, efficient reverse genetic systems of orthotospoviruses still remain to be developed as well as stable insect cell cultures for *in vitro* orthotospovirus propagation. The availability of editing DNA tools as CRISPR Cas9 may allow relevant changes in how to control orthotospovirus infection from dismissing key elements in plant hosts necessary for virus infection.

Monocistronic RNA that encodes for only one polypeptide.

Reassortment Exchange of genomic segments between viruses.

Introduction

The only three virus species of this genus were described a long time ago. Since then, only a handful of articles have been published, mainly concerning Ourmia melon virus (OuMV), the type species. The other two members of the genus are Cassava virus C (CsVC), reported only once in a mixed infection in cassava from Malawi, and Epirus cherry virus (EpCV), found in a single cherry tree. This tree has since died. OuMV has been detected on several occasions in melons in north-western Iran. In general, OuMV has been found in mixed infections with other cucurbit viruses, so the extent of economic losses is unknown. Ourmiaviruses are potentially damaging, as they have been experimentally transmitted to a rather wide range of dicot species, including important crops in which they produce symptoms of mosaic, mottle, and necrosis.

Taxonomy, Phylogeny and Evolution

The genus is not assigned to a specific family. The members have the same structural features but their coat proteins (CPs) share less than 70% aa identity. Phylogenetic analysis of the ourmiavirus RdRp places them in a clade originated from ourmia-like viruses of invertebrates, infecting members of the subphylum Chelicerata and Crustacea, and of the superphylum Lophotrochozoa. This clade was shown to be sister to the one containing ourmia-like mycoviruses. Such a phylogeny suggests that ourmia-like viruses infecting fungi, crustacea, and plants could belong to distinct genera in the same virus family. These genera are distinct from the *Narnavirus* genus. Since most of the ourmia-like viruses have been found in invertebrates, it has been hypothesized that the plant ourmiaviruses evolved by horizontal virus transfer (HVT) from herbivorous invertebrates. In the new host the acquisition of a movement protein (MP) from a plant virus was necessary. Actually, analyses of the ourmiavirus MP indicates similarities with the MPs of viruses in the family *Tombusviridae*. The CP of ourmiaviruses shows distant affinities with the CPs of sobemo-, tombusluteo- and nodaviruses. As of 2017, three species in the genus *Ourmiavirus* were recognized by ICTV: *Cassava virus C* (CsVC), *Epirus Cherry Virus* (EpCV), and *Ourmia melon virus* (OuMV).

Virion Structure

The virions are non-enveloped and made of subunits of a single CP (Fig. 1). They have cylindrical bodies of discrete lengths, 18 nm in diameter and capped by conical (probably hemi-icosahedral) ends. The bodies of the particles are composed by a series of disks, commonly two or three for particles with a length of 30–37 nm, more rarely four or six disks for particles with a length of 45.5–62 nm. Particles with five disks and with a hypothetical length of 54 nm have never been observed. The buoyant density in CsCl of the particles of all sizes is 1.375 g cm⁻³.

Genome Organization

Viruses in this genus have a tripartite single stranded positive sense RNA genome. Each genomic segment is monocistronic. The lengths of the genomic segments are approximately 2800 nt, 1100 nt and 970 nt (Fig. 2).

Properties and Functions of Gene Products

Each genomic segment contains a single ORF. RNA1 encodes for a putative RdRp of ca. 860 aa and 97 kDa, RNA2 for a putative MP of ca. 290 aa and 32 kDa, and RNA3 for a putative CP of ca. 200 aa and 23 kDa ([Fig. 2](#)). The functions of the RdRp, MP and CP have been experimentally demonstrated for OuMV, the better characterized virus in the genus. OuMV RdRp is necessary for virus replication and contains the polymerase motif GDD.

OuMV MP belongs to the "30K" Superfamily of movement proteins. It is a symptoms determinant, is localized at plasmodesmata of infected plant cells and forms tubular structures inside the cytoplasm and between adjacent cells. The OuMV CP is required for assembly of the virions and systemic movement. It is localized in the nucleolus when expressed as fusion with GFP and without the expression of RNA1 and RNA2. The KR-rich region at the N-terminus of the CP has been shown to induce tissue tropism, to be a host determinant and to interfere with the plant silencing pathway. Virion assembly requires an active replication and RNA3, but not RNA2.

Replication and Propagation

OuMV replication occurs in the cytoplasm of infected plant cells. OuMV MP is required for cell-to-cell movement. While effective systemic infection requires the expression of the OuMV CP, RNA1 and 2 can move up to some vascular tissue exit sites without CP expression.

Transmission, Host Range

Ourmiaviruses are plant infecting viruses. OuMV was isolated from melon, CsVc from cassava and EpCV from cherry. Extensive surveys have not been conducted to reveal other natural hosts of these viruses in the geographic areas where the 3 species were originally isolated, aside from one survey in Iran on cucurbits. Experimentally, OuMV and other ourmiaviruses have been mechanically transmitted to dicots in ca. 15 plant families, including Solanaceae, Brassicaceae and Cucurbitaceae. Transmission studies found that these viruses could not be transmitted by several aphid species, the whiteflies *Trialeurodes vaporariorum* and *Bemisia tabaci*, and the mite *Tetranychus urticae*. Transmission experiments via soil or water were also unsuccessful. Seed-transmission rates in *Nicotiana benthamiana* and *N. megalosiphon* are 1%–2%.

Epidemiology and Control

Not much is known about the epidemiology of these viruses. A survey conducted on melon and squash in 16 regions in Guilan Province (Iran) in 2005 and 2006 revealed that OuMV was present in 4 regions. Based on this survey, OuMV was the most prevalent virus detected in melon (*Cucumis melo* L.) and was frequently found in squash (*Cucurbita* sp.). Based on the limited information available, standard agronomic practices aimed at reducing the economic damage caused by ourmiaviruses could include screening for virus presence in seeds and other plant propagative material, exclusion and eradication in areas where the viruses are not present, and rouging of symptomatic plants.

Virus–Host Relationships

Plants systemically infected with ourmiaviruses show an array of symptoms, such as vein chlorosis, rasp-leaf, necrotic spots and rings, stunting, yellowing and necrosis.

Diagnosis

Virions and tubular structures of OuMV have been used to produce species specific polyclonal antibodies for ELISA and western blotting, but commercial diagnostic kits are not available. PCR primers used in published experiments can be adopted for diagnosis via molecular techniques.

Concluding Remarks

Due to the little effort dedicated so far to this genus, in spite of its very special characteristics, many questions remain unsolved. Evidence from metagenomics suggests that the origin of this genus could have been genomic reassortment of RNA viruses infecting hosts outside the plant kingdom, accompanied by HVT. More studies are necessary to elucidate the missing information about this interesting genus.

Glossary

Gene silencing Plant defense mechanism based on the detection and fragmentation of double-stranded RNAs, including the replicative forms of RNA viruses.

Mild-strain cross-protection A plant systemically infected by a mild virus strain will not develop additional symptoms when inoculated by a severe strain of the same virus.

Molecular clock The molecular clock hypothesis considers that mutations between homologous nucleotide or amino-

acid sequences accumulate in a clock-like fashion, i.e., at a constant rate with time. Molecular changes along the branches of a phylogenetic tree can thus be used to estimate the time of divergence from a common ancestor.

Pathogen-derived resistance Engineered resistance to pathogens through the synthesis in transgenic plants of pathogen proteins or nucleic acids.

History and Taxonomy

The term Papaya ringspot virus (PRSV) was first used in the 1940s to describe a viral disease of papaya, initially observed in Hawaii. The name was used primarily to describe the ringspots that appeared on fruits from infected plants. Early investigations showed that the virus was transmitted by several species of aphids in a non-persistent manner. That is, the aphid vector could acquire the virus in a short period of time while feeding on infected plants and likewise transmit the virus in a span of few seconds to less than a minute during subsequent feeding. In the same decade researchers from India and other places like Puerto Rico reported the occurrence of an aphid-transmitted disease of papaya; based on the symptoms on the leaves, it was identified as Papaya mosaic virus. Work in the 1980s showed that the aphid-transmitted papaya mosaic virus and PRSV were the same virus, and the name of PRSV was adopted. PRSV is a member of the family *Potyviridae*, a large and arguably the most economically important group of plant viruses. Today, the term *Papaya mosaic virus* (PapMV) is reserved for a virus that is not aphid transmitted, belonging to the genus *Potexvirus* in the family *Alphaflexiviridae*, and causes the papaya mosaic disease which is seldom observed and not important commercially, even if mixed infections between PRSV and PapMV can increase symptoms and virus accumulation. PRSV should not be confused with another potyvirus, *Papaya leaf distortion mosaic virus* (PLDMV), which occurs in Okinawa and other parts of Asia, such as Taiwan. This virus causes very similar symptoms as PRSV on papaya and cucurbits but is serologically unrelated and its sequence shares only 55%–59% similarity to that of PRSV.

In the 1930s a mosaic disease was described in cucurbits in the USA and named Watermelon mosaic virus (WMV). Later on, biological and serological studies showed that the disease might be caused by two distinct viral entities called WMV-1 and WMV-2. More recently, serological and molecular characterization showed that PRSV and WMV-1 are virtually identical. Based on their close relationship, a single name was adopted to unify both viruses into one species. The name PRSV was chosen due to its being named before WMV-1. To clarify host range, 'P' (PRSV-P) or 'P type' is used to designate virus infecting papaya and cucurbits, while 'W' (PRSV-W) or 'W type' refers to virus infecting cucurbits only.

Classification and Relationship With Other Potyviruses: The “PRSV Cluster”

PRSV was classified as a member of the genus *Potyvirus* in the family *Potyviridae* based on particle morphology, aphid transmissibility, serological relationships, ability to induce pinwheel cytoplasmic inclusions in host cells, genome organization and nucleotide (nt) sequences. Several other potyviruses infect papaya or cucurbits. The main other potyvirus infecting papaya is PLDMV, that shares no particular relationship with PRSV. More than 10 potyviruses infect cucurbits. Some of them are not closely

related to PRSV based on serological and molecular data: Zucchini yellow mosaic virus (ZYMV), Watermelon mosaic virus (WMV), Melon vein banding mosaic virus (MVBV), Telfairia mosaic virus (TeMV), Cucurbita vein-banding virus (CVBV), Turnip mosaic virus (TuMV), Clover yellow vein virus (CIYVV) and Bean yellow mosaic virus (BYMV). However, in the 1990s, several viral isolates, mostly infecting cucurbits, were found to share biological and serological relationships with PRSV, forming what was called a “PRSV cluster” of related members that could not always be unambiguously distinguished. When sequences became available, the different criteria of the International Committee for the Taxonomy of Viruses (ICTV) could be applied, mainly: (1) less than 76% nt identity (80% aa identity) in the coat protein (CP)-coding region or in the whole genome; (2) difference in polyprotein cleavage site; (3) host range and key host reactions; (4) different inclusion body morphology; (5) serological relatedness. Partial or complete sequences have revealed the presence of at least seven species besides PRSV in the “PRSV cluster”: Moroccan watermelon mosaic virus (MWMV), Algerian watermelon mosaic virus (AWMV), Zucchini yellow fleck virus (ZYFV), Zucchini tigre mosaic virus (ZTMV), Zucchini shoestring virus (ZSTV), Sudan watermelon mosaic virus (SuWMV) and Wild melon vein banding virus (WMVBV). Partial sequences suggest that more species are present in Asia, although they remain to be fully characterized (Fig. 1). Most members of the PRSV cluster were found in a limited geographic area and/or presented a low prevalence in the countries where they were present. AWMV, MWMV, SuWMV, WMVBV, ZYFV and ZSTV were found only in Africa and/or the Mediterranean Basin, indicating that this region is most probably their center of origin. ZTMV was found in Europe, Asia, America and Africa but at a rather low prevalence, although it has probably been frequently mis-diagnosed as PRSV because of the frequent cross-reactions observed in serological tests.

Host Range, Symptomatology, and Geographic Distribution

The systemic host range of PRSV is confined to plants in the families *Caricaceae* and *Cucurbitaceae*, with the primary economically important host being papaya and a range of cucurbits such as squash, cucumber, watermelon, and melons. PRSV-P isolates cause generally severe symptoms in papaya and mild symptoms in cucurbits, while PRSV-W do not infect papaya and cause severe symptoms in cucurbits. In addition, some PRSV isolates cause local lesions on plants of the family *Chenopodiaceae* such as *Chenopodium quinoa* and *C. amaranticolor*. In papaya, PRSV infection is characterized by mosaic and chlorosis symptoms on leaves, water-soaked streaks on the petiole, and deformation of leaves that can result in shoestring-like symptoms that resemble mite damage (Fig. 2). The virus can cause deformation and ringspot symptoms on the fruit, hence the name PRSV. PRSV-P is present in all papaya-growing areas. PRSV-W infects cucurbits worldwide, but is more prevalent in tropical, subtropical and Mediterranean conditions than in temperate ones. This may be related to the difficulty for the virus to overwinter in areas where cucurbits are not present all year round. On cucurbits, PRSV-W causes severe mosaic and chlorosis on leaves, which are also often deformed with shoestring-type symptoms. The fruits are often deformed and bumpy. Some PRSV-W isolates induce systemic necrotic spots and top necrosis in some melon cultivars.

Transmission and Epidemiology

PRSV is transmitted in a non-persistent manner by more than 24 aphid species among which *Aphis gossypii*, *Myzus persicae* and *A. craccivora* are the most efficient. PRSV is acquired and transmitted during very short probes, what makes its spread within a field generally rapid. However PRSV persists only few hours on the stylets: therefore long-distance spread by aphids is limited. Virus sources are generally neighboring infected crops, but for PRSV-W several wild cucurbits (*Melothria pendula*, *Momordica* sp.) were shown efficient virus sources in tropical and sub-tropical regions. There is no report of PRSV-P or -W seed transmission. Long-distance spread may occur through the movement of infected material (seedlings, fruits). Indeed, aphids were shown to be able to acquire and transmit efficiently PRSV-W from commercial infected melon fruits.

General Properties and Genome of PRSV

Like other potyviruses, PRSV has flexuous filamentous particles about 760–800 nm × 12 nm encapsidating a single-stranded RNA of about 10,326 nt in length. The genome is translated as a single polyprotein that is further cleaved autocatalytically in 10 functional proteins (P1, HC-Pro, P3, 6K1, CI, 6K2, NIa-VPg, NIa-Pro, NIb and CP), with a smaller 11th protein P3N-PIPO expressed through translational frameshift. Virus particles consist of 94.5% protein and 5.5% nucleic acid by weight. PRSV has a single coat protein (CP) of about 36 kDa. The density of the virion in purified preparations is 1.32 g cm⁻³ in cesium chloride.

A rather interesting feature of the PRSV is that sequence analysis predicts two potential cleavage sites at the N-terminus of the CP. One of the sites (VFHQ/SKNF) predicts a CP of 33 kDa and a polymerase (nuclear inclusion b protein, NIb) of 537 aa about 20 aa larger than those of other potyviruses. The second predicted cleavage site (VYHE/SRGTD) generates a CP of 36 kDa and a NIb of 517 aa. There is no firm evidence to suggest that only one cleavage site is used. If both sites are used in polyprotein processing, one would expect heterogeneous products. This may explain why the analysis of purified CP preparations that are stored frequently shows the major ~36 kDa form and CPs that are 2–5 kDa smaller.

Fig. 1 Taxonomy, based on coat protein nucleotide sequences, of potyviruses in the “PRSV cluster” including PRSV, six acknowledged species and two putative new species. PRSV-P isolates of PRSV infect papaya whereas PRSV-W isolates infect cucurbits. Branch lengths indicate the molecular divergence of viruses (the scale bar represents 0.05 mutations per residue). Figures at some nodes represent bootstrap values (in %), indicating the robustness of each node. Only values above 75% are indicated.

Sequence Diversity and Evolution; Molecular Clock Analyzes

Knowledge of the sequence diversity among isolates of a virus has great implications in developing an effective virus disease management program and in understanding the origin and biology of the virus. Numerous PRSV-P and -W sequences from virus isolated from different parts of the world have been reported. Nucleotide and aa sequences among PRSV isolates differ by as much as 21% and 13% respectively. Heterogeneity in CP length ranging from 837 to 870 nt has been noted, resulting in CPs of between 279 and 290 aa. The first 50 or so aa of the N-terminal region of the PRSV CP gene are highly variable and all differences in CP length were confined to this region. The N-terminal part of PRSV CP is characterized by the presence of several –up to 8-Glutamic acid (E) and Lysine (K) repeats, and the majority of the size differences were due to differences in the number of EK repeats.

Phylogenetic analyzes based on HC-Pro and CP nt sequences indicated the presence of two main clades of PRSV isolates, one from Asia and one from Africa, Australia and America. Isolates from India presented a basal location in the phylogenetic tree, suggesting that the Indian Peninsula could correspond to the center of origin of the virus. Two major radiations appear to have arisen from different branches of the Indian population. The earliest included all the isolates in east and south east Asia (China, Indonesia, Malaysia, Philippines, Taiwan, Thailand and Vietnam). The other includes all the isolates from the Americas and Europe with small separate sub-clusters of isolates from Hawaii, Taiwan, and Australia. A “molecular clock” approach, relying on the hypothesis that mutations accumulate in viral populations at an almost constant yearly rate, was applied to PRSV. Based on the molecular divergence between the Indian basal group and the “American” lineage, PRSV introduction to America presumably happened about 300 years

Fig. 2 Symptoms of PRSV-P on papaya (left) and of PRSV-W on zucchini (right, top) and on melon (right, bottom).

ago, maybe through Europe. Isolates from the “Asian” cluster have been observed recently in Europe and the Caribbean, showing that population exchanges are currently taking place, probably through the worldwide trade of plant materials.

There was no relationship between the biotype (W or P) and the viral phylogeny, suggesting that jumps between W and P happened several times during the evolution of the virus. Evidences from various sources suggest that PRSV is primarily a pathogen of cucurbits, and that PRSV-P originated from PRSV-W. This suggestion is supported by the diversity in cucurbit-infecting potyviruses that are phylogenetically related to PRSV. In Australia, the outbreak of PRSV-P about 25 years ago most probably arose from the population of PRSV-W already present in the country.

Molecular Determinants for Biological Properties

The easy jump between PRSV-W and PRSV-P pathotypes suggested a simple genetic determinism related to a few mutations. Studies utilizing infectious transcripts from recombinant viruses followed by bioassays of the transcripts have demonstrated that the region of PRSV genome encoding the NIa-Protease was critical for papaya infection. In particular, two aa at positions 2309 (K → D) and 2487 (I → V) of PRSV are significantly different between papaya-infecting type P and non-papaya-infecting type W. Further point mutational studies in these sites indicated that the K → D mutation was responsible for conferring the ability to infect papaya.

As noted earlier, PRSV causes local lesions on *C. amaranticolor* and *C. quinoa*. The severe strain PRSV HA strain from Hawaii causes local lesions on *C. quinoa* but a mild nitrous acid mutant of it, PRSV HA 5-1, does not. Recombinant infectious viruses were generated by exchanging genome parts between PRSV HA and PRSV HA 5-1. The study revealed that the pathogenicity-related region is present between nt positions 950 and 3261 of the PRSV HA genome and mutations in the P1 and HC-Pro resulted in the attenuation of PRSV HA symptoms and the loss of ability to produce local lesions on *C. quinoa*. The HC-Pro coding region of PRSV is thus the major determinant factor for local lesion formation.

Contrary to other potyviruses where the N-terminal part of the HC-Pro is dispensable for infectivity, this region was shown to be required in PRSV-W for systemic infection of zucchini. Virus–host interaction studies based on recombinant analyzes between severe and mild strains of PRSV indicated that the HC-Pro gene plays an important role in viral pathogenicity and virulence and acts as a suppressor of the gene-silencing defense mechanism in the papaya host plant. In addition, the comparative reaction of recombinant PRSV with chimeric CP gene sequences showed that heterologous sequences and their position in the CP gene influences their pathogenicity on PRSV-resistant transgenic papaya. As with other potyviruses the HC-Pro/virions interaction is essential for aphid transmission of PRSV.

Diagnostics

As for many other potyviruses, serological methods (DAS-ELISA) are widely used for PRSV diagnostics. Polyclonal antibodies against purified virus particles have been obtained, and commercial DAS-ELISA kits are available. However serological cross-reactivity between viruses in the “PRSV cluster” can be observed, potentially resulting in misdiagnosis. Since many PRSV CP or complete sequences are now available, specific primers have been designed for the molecular diagnostic of PRSV using reverse transcription and polymerase chain reaction (RT-PCR), alone or in multiplex with other papaya- or cucurbit-infecting viruses. More recently, isothermal amplification techniques (LAMP) have been developed for PRSV.

Virus Control

Cultural Practices: Prophylactic Measures

Prophylactic measures are not specific to one virus. They generally tend to prevent or limit the contact of viruliferous aphids with susceptible crops. Insecticide treatments are usually inefficient for non-persistently transmitted viruses. The control or management of PRSV on papaya has been approached through practices such as quarantine, eradication, avoidance by planting crops in areas isolated from the virus, and continual rogueing of infected plants. In Taiwan a successful but costly method used was the cultivation of papaya under insect proof nets.

For cucurbits, the same precautions can be used, particularly through careful weeding near plantings and avoiding overlapping crops in the same areas to reduce virus and aphid sources. Besides, plastic mulches are frequently used, as they limit weeds but they also have a repelling effect on aphids and contribute to delay virus spread, at least at the beginning of the crop before the plants grow and cover most of the mulch surface. Different covers (plastics, unwoven) can also be used to prevent winged aphids from reaching low-growing cucurbit plants, but they must be removed to allow pollination.

Cross-Protection

Cross-protection can be defined as the use of a mild strain of virus to infect plants that are subsequently protected against economic damage caused by a severe strain of the same virus. This practice has been used successfully for many years to minimize damage by Citrus tristeza virus in Brazil, for example. In the early 1980s, a mild strain of PRSV (described above as PRSV HA 5-1) was developed through nitrous acid treatment of a severe strain, PRSV HA isolated from Oahu Island in Hawaii. This mild strain was tested on Oahu Island and showed good protection against damage by severe strains but produced symptoms that were very obvious on certain cultivars, especially in the winter months. This prominent symptom induction on certain cultivars and the logistics of mild strain buildup and inoculation of plants, among others, were factors that caused it not to be consistently used on the island of Oahu. Interestingly, the mild strain was used extensively for several years in Taiwan, but it did not afford sufficient protection against the severe strains from Taiwan and thus its use was abandoned after several years.

Breeding for Resistance

The use of resistant cultivars, when they are available, is the easiest and cheapest way for farmers to control plant viruses. However resistance must be present in the germplasm of the species of interest, and introducing the resistance in commercial cultivars is a time-consuming process. It is important, before starting the breeding process, to check if the resistance is not broken by preexisting virus strains, or if the virus can easily evolve to overcome it.

Research to develop PRSV-resistant papaya varieties started in the 1970s. Since resistance to PRSV has not been identified in *Carica papaya*, researchers have used tolerant germplasm in an attempt to develop papaya cultivars with acceptable PRSV tolerance and horticultural characteristics. However, tolerance to PRSV is apparently governed by a family of genes that is inherited quantitatively, which makes it technically difficult to develop cultivars of acceptable horticultural quality. Furthermore, the tolerant lines do become infected with PRSV, although fruit production continues still at a lower level. Indeed, in Thailand, the Philippines, and Taiwan, a number of tolerant lines have been developed and are used. However, tolerance could not be introduced in all types of papayas and infected tolerant plant may act as virus sources to contaminate susceptible crops.

Resistance to PRSV has been described in the germplasm of different cucurbits, including melon, cucumber, squash and watermelon. The resistance was characterized in most cases as monogenic, either dominant or recessive. Interestingly in melon, a dominant resistant gene was found efficient for PRSV-W as well as for several other virus species of the “PRSV cluster”. Resistance is now present in several commercial cultivars of melon, cucumber and squash.

Pathogen-Derived Resistance for Controlling PRSV: The Hawaii Case

The control or management of PRSV in Hawaii has been approached through cultural practices, cross-protection with mild virus strains, tolerance, and resistance using the “pathogen-derived resistance” technology. Ultimately, the most successful has been the “pathogen-derived resistance” approach.

PRSV was first detected in the 1940s on Oahu Island where Hawaii's papaya industry was located at that time. Efforts to control the virus on Oahu largely consisted of state officials and farmers continually monitoring for infected plants and rogueing them, especially in areas where the virus was not prevalent. However, by the late 1950s, PRSV was causing extensive damage, which caused the papaya industry to relocate to Puna on the island of Hawaii.

The relocation of the industry to Puna was timely and effective because Puna had an abundance of land that was suitable to grow Kapoho, a cultivar of excellent quality that adapted to the volcanic soil base there, allowing excellent drainage, had high rainfall and yet lots of sunshine, and the land there could be bought or leased at reasonable prices. By the 1970s, the Kapoho papaya grown in Puna accounted for 95% of the state's papaya production, making papaya the second most important fruit crop behind pineapple.

Despite strict quarantine on movement of papaya seedlings between islands, PRSV was discovered in Puna in May 1992 ([Fig. 3\(a\)](#)) and the Hawaiian papaya industry would be forever changed. By 1995, a third of the papaya growing area was completely infected and much of the rest of Puna had widespread infection ([Fig. 3\(b\)](#)). By 1998, the production of papaya in Puna had dropped to 27 million pounds of papaya from 52 million pounds in 1992 when PRSV was discovered in Puna. In retrospect, the efforts of quarantine, monitoring and rogueing of infected plants in Hilo, and suppression efforts of PRSV in Puna all played key roles in helping Hawaii's papaya industry, because it gave researchers time to develop control measures for PRSV.

Transgenic Resistance

In the late-1980s, an exciting development on Tobacco mosaic virus (TMV) provided a rationale that resistance to plant viruses could be developed by expressing the viral CP gene in a transgenic plant. This approach was called CP-mediated protection, and, at about the same time, a report introduced the concept of "parasite-derived resistance". The report on transgenic resistance to TMV set off a flurry of work in many laboratories to determine if this approach could be used for developing resistance to other plant viruses. Likewise, work was initiated in 1985 to use this approach for developing PRSV-resistant transgenic papaya for Hawaii.

Key requirements for successful development and commercialization of transgenic virus-resistant plants are the isolation and engineering of the gene of interest, vectors for mobilization into and expression of the gene in the host, transformation and subsequent regeneration of the host cells into plants, effective and timely screening of transformants, testing of transformants, and the ability to deregulate and commercialize the product.

The CP gene of the mild strain of PRSV was chosen as the "resistance" gene because it had been recently cloned and it was of the PRSV P type. The commercial cultivars Kapoho, Sunrise, and Sunset were chosen for transformation. In 1991, tests of the R0 lines identified a transgenic Sunset that expressed the CP gene of PRSV HA 5-1, and showed resistance to PRSV from Hawaii. A field trial of R0 plants was started in April 1992 on as the island of Oahu, and a month later PRSV was discovered at Puna in May 1992, as discussed above.

The Oahu field trial showed that R0 plants of line 55-1 were resistant, and line 55-1 was further developed to obtain the cultivar "SunUp" which is line 55-1 that has the CP gene in a homozygous state, and "Rainbow" which is an F1 hybrid of SunUp and the non-transgenic "Kapoho". SunUp is red-fleshed and Rainbow is yellow-fleshed. In 1995, SunUp and Rainbow were tested in a subsequent field trial in Puna and showed excellent resistance ([Fig. 3\(c\)](#)). Due to its yellow flesh and good shipping qualities, Rainbow was especially preferred by the growers. Line 55-1 was deregulated by the US government and commercialized in May 1998. The deregulation also applied to plants that were derived from line 55-1. The timely commercialization of the transgenic papaya in 1998 was crucial since PRSV had decreased papaya production in Puna by 50% that year compared to 1992 production levels. The transgenic Rainbow papaya was quickly adopted by growers and recovery of papaya production in Hawaii was underway ([Fig. 3\(d\)](#)). The transgenic papaya is sold throughout Hawaii ([Fig. 3\(e\)](#)) and the mainland USA, and to Canada where it was deregulated in 2003. Japan, the main importer of Hawaii-grown papaya, approved transgenic papayas for import in 2011. However, several challenges remain: coexistence, exportation, deregulation, and the adoption of transgenic papaya in other countries that suffer from PRSV. The use of transgenic papayas in Hawaii has now been going on for more than 20 years and the resistance is still highly durable.

One limitation of larger-scale deployment of the transgenic papayas lies in the fact that the efficiency of resistance is related to the percentage of identity between the transgene and the challenging PRSV isolate: the transgenic papayas from Hawaii were found susceptible to PRSV isolates from Hainan. The success of transgenic papaya in Hawaii has encouraged other papaya-cultivating states and countries to develop transgenic papayas resistant to their local PRSV strains. Transgenic varieties have thus been developed in America (Florida, Brazil, Venezuela, Jamaica), Asia (China, Indonesia, Malaysia, the Philippines, Taiwan) and Australia. Depending on the construct and the country, the plants were more or less resistant, ranging from complete and durable resistances to easily broken ones. Resistance-breaking could be related to the emergence of new strains that presented a reduced sequence identity with the transgene. In Taiwan, a transgenic papaya initially conferred resistance to PRSV, but the plants became infected with the emerging PLDMV. Transgenic papayas containing partial CP genes of PRSV and PLDMV conferred resistance to both viruses, but the resistance was later broken by a recombinant "super-strain" of PRSV. This shows that viral diversity and rapid evolution remain challenging for a durable control. Pathogen-derived resistance appears as the most effective way to control papaya ringspot disease, but its use should be associated with a good knowledge of the local viral diversity and the use of cultural practices for an integrated management of PRSV.

Although the transgenic approach was not as successful to control PRSV-W in cucurbits, it is used in the USA to control ZYMV, WMV and Cucumber mosaic virus in squash. Interestingly a commercial squash cultivar possessing transgenic resistance to these three viruses and conventional resistance to PRSV-W shows a good protection against these four viruses.

(c) Field trial of transgenic papaya in Puna in 1994: PRSV-resistant transgenic papaya (center) surrounded by PRSV-infected non-transgenic papaya (d) Commercial planting of transgenic papaya one year after releasing seeds of PRSV-resistant transgenic papaya. (e) Transgenic papaya commonly sold in supermarkets. (f) Risk of growing non-transgenic papaya still exists (photograph from 2005). Foreground is PRSV-infected non-transgenic papaya that are cut, and background shows healthy PRSV-resistant transgenic papaya.

Summary Remarks

PRSV has been thoroughly characterized and is a typical member of the family *Potyviridae*, arguably the largest and economically most important plant virus group. The complete genome sequence has been elucidated and infectious transcripts have provided a means to determine the genetic determinants of some important biological functions such as host range and virulence. Furthermore, pathogen-derived resistance has been used to control PRSV-P in Hawaii through the use of virus-resistant transgenic papaya. The transgenic virus-resistant papaya provides a potential means to test the global acceptance of genetically modified (GM) organisms while presenting a plausible approach to control a disease affecting papaya worldwide. In order to avoid resistance-breaking, GM papayas presenting resistance to local strains should be included in an integrated pest management of PRSV.

Glossary

Forma specialis An informal rank in a classification, allowed by the International Code of Nomenclature for Algae, Fungi, and Plants, that is applied to a parasite (most frequently a fungus), which is characterized from a physiological standpoint (e.g., by the ability to infect a specific host), but scarcely or not at all from a morphological standpoint.

Fortuitous hosts of obligate biotrophic

Plasmodiophorida Host on which some primary infections evolve into resting spores without going through the zoosporangial stage.

Hetero-encapsidation Partial or full coating of the genome of one virus with the coat protein of a differing

virus. Also termed trans-capsidation or heterologous encapsidation.

Leaky scanning Mechanism by which the ribosomes fail to initiate translation at the first AUG start codon and scan downstream for the next AUG codon.

Obligate endoparasite A parasitic organism that cannot complete its life cycle without exploiting a suitable living host, and that lives within that host.

Post-transcriptional gene silencing Mechanism for sequence-specific RNA degradation in plants.

Triple gene block A specialized evolutionarily conserved gene module involved in the cell-to-cell and long-distance movement of plant viruses.

History

Peanut (groundnut, *Arachis hypogaea*) clump disease, characterized by severe stunting and clumping, was first described from India in 1927 and subsequently from West Africa in 1931. The causal agent in West Africa as well as in India was identified as a virus, *Peanut clump virus* (PCV) and *Indian peanut clump virus* (IPCV), respectively. Annual losses to the peanut crop due to PCV and IPCV were estimated to exceed US\$38 million in the late 1990s. Pecluviruses also cause diseases on several dicotyledonous and monocotyledonous crops.

Taxonomy and Classification

The genus *Pecluvirus* has only two species, isolates from West Africa were grouped under the species *Peanut clump virus* (Peanut clump virus; PCV) and those from the Indian subcontinent were grouped under the species *Indian peanut clump virus* (Indian peanut clump

virus; IPCV). The two virus species were initially assigned to the genus *Furovirus* mainly based on virion morphology and vector transmission by *Polymyxa graminis* (Rhizaria, *Phytomyxea*, *Plasmodiophorida*). Subsequently, based on molecular features, the ICTV in 1997 assigned PCV and IPCV to the newly established genus *Pecluvirus* (siglem from Peanut clump virus). They differ in their geographical distribution, host range, antigenic properties and genomic sequences. Later, the genera *Tobamovirus*, *Tobravirus*, *Hordeivirus*, *Furovirus*, *Pecluvirus*, *Pomovirus*, and *Goravirus* were assigned to the newly established family *Virgaviridae* (from the Latin *Virga*, meaning rod).

Geographic and Seasonal Distribution

PCV occurs in Burkina Faso, Benin, Chad, Congo, Côte d'Ivoire (Ivory Coast), Niger, Mali, Gabon, Senegal, and Sudan, and IPCV in the Indian states of Punjab, Andhra Pradesh, Telangana, Tamil Nadu, Rajasthan, Haryana, and Gujarat, and in Pakistan (Sind and Punjab provinces). IPCV and PCV infections are noticed mainly in the peanut crops cultivated during the rainy season (July–November in India and April–October in West Africa). Nevertheless, post-rainy season crops can also be infected.

Host Range and Symptoms

PCV infects peanut, cowpea, sugarcane, maize, sorghum, pearl millet, and finger millet, whereas IPCV infects peanut, cowpea (*Vigna unguiculata*), pigeonpea (*Cajanus cajan*), chili (*Capsicum annuum*), wheat (*Triticum aestivum*), barley (*Hordeum vulgare*), maize (*Zea mays*), sorghum (*Sorghum bicolor*), pearl millet (*Pennisetum glaucum*), foxtail millet (*Setaria italica*), and finger millet (*Eleusine coracana*). *Cynodon dactylon*, *Cyperus rotundus*, *Oldenlandia aspera*, and *Vigna subterranea* (bambara groundnut) that can play a significant role in both virus survival and dissemination.

Fig. 1 Symptoms induced by Peanut clump virus (PCV), in West Africa. (a) field-infected peanut plants occurring in patches of various sizes, intercropped with pearl millet in Maradi, Niger Republic, (b) peanut leaflets showing initial symptoms of chlorosis and mild mosaic, (c) chlorosis along the veins resembling oak leaf, (d) PCV-infected sugarcane plants exhibiting red leaf mottle in Burkina Faso, (e) IPCV and PCV vector, *Polymyxa graminis*, in transversal section of sorghum roots, stained with lactophenol blue showing zoosporeangia, (f) sporosori, bars represent 25 µm. Photographs courtesy of P. Delfosse.

Fig. 2 Symptoms induced by Indian peanut clump virus (IPCV) on various hosts. (a) on peanut plants showing severe stunting, occurring in patches in the field, and an apparently uninfected plant, (b) young peanut leaflets with initial symptoms of chlorosis and mosaic symptoms, (c) early infected pigeonpea plants showing severe stunting with an apparently uninfected plant, (d) inset showing chlorotic symptoms on young pigeonpea leaflets (left) and by its side leaflets from healthy plant, (e) infected wheat plants occurring in patches, (f) early infected wheat plants showing dark green leaves and chlorotic streaks, (g) late infected wheat plants showing panicle formation. Seed derived from them can transmit IPCV up to 1%, (h) early infected barley plants showing stunting and severe yellowing. Photographs courtesy of P. Delfosse.

Diseased peanut plants are conspicuous under field conditions because of their dark green appearance, stunting, and occurrence in patches (Fig. 1(a) and Fig. 2(a)). The disease incidence is high in fields where peanut crops are grown in rotation with wheat, barley, and pearl millet. Early-infected peanut plants often did not yield pods and late-infected crops showed decreased crop yields up to 60%.

In peanut, the symptoms incited by PCV are essentially similar to those induced by IPCV. In West Africa, peanut clump disease symptoms are often confused with green rosette because of the presence of stunted dark green plants occurring in patches in the fields. The peanut clump disease occurs in the same areas year after year with marginal increase in the periphery of the patches in the successive peanut crops. Initial symptoms on young leaflets of peanut are mottling, mosaic and chlorotic veins or the 'oak leaf symptom' (Fig. 1(b) and (c), Fig. 2(b)). When such leaflets mature, they turn dark green with or without faint mottling. Late infected plants may not show conspicuous symptoms and clumping is restricted to a few branches in some plants. PCV causes the red leaf mottle disease in sugarcane (*Saccharum officinarum*) (Fig. 1(d)).

Pigeonpea plants infected with Hyderabad isolate of IPCV (IPCV-H) showing stunting are presented in Fig. 2(c). Fig. 2(d) shows chlorosis on infected pigeonpea leaflets, left, and uninfected leaflets, right. Wheat plants, up to three weeks old, infected by IPCV-H show rosette symptoms similar to those caused by the *Soil-borne wheat mosaic virus* (SBWMV) and grain yield losses up to 58% are recorded. Wheat cultivar RR-21 infected with IPCV-H showing stunting is presented in Fig. 2(e). Early infected wheat plants show chlorotic streaks (Fig. 2(f)) and will produce panicles (Fig. 2(g)). Seed from these plants can transmit IPCV up to 1%. Barley plants infected with IPCV-H are stunted and bushy with chlorotic or necrotic leaves (Fig. 2(h)) and the majority of these plants die. The plants that reached maturity produced poorly developed spikes. IPCV-H also infected pearl millet, finger millet, foxtail or Italian millet, and sorghum plants. In maize IPCV-H caused aerial biomass losses up to 33% and grain loss up to 36%.

Various isolates of PCV and IPCV are readily detected in the cells of roots, stems, and leaves of systemically infected hosts. In wheat cells, PCV particles are found in the cytoplasm, near the nucleus or along the plasmalemma, and arranged in angled-layer aggregates.

In experimental host range studies by sap inoculation, PCV and IPCV infected a wide range of both dicotyledonous and monocotyledonous plants. For IPCV, *Nicotiana clevelandii* x *N. glutinosa* hybrid and *Phaseolus vulgaris* (cv. Top crop) are suitable for virus propagation and as assay/diagnostic hosts, respectively. *Chenopodium amaranticolor* and *C. quinoa* are local lesions hosts. IPCV isolates collected from clump diseased peanut crops from different locations in India differ slightly in their host ranges. *Canavalia ensiformis* and *N. clevelandii* x *N. glutinosa* hybrid are found to be useful for differentiating the isolates of IPCV. In the case of PCV, *C. amaranticolor*, *N. benthamiana*, *N. glutinosa*, *P. vulgaris*, and *Triticum aestivum* are of diagnostic value. *N. benthamiana* and *P. vulgaris* are suitable for virus propagation. The symptoms induced in *C. amaranticolor* by various PCV isolates collected from Burkina Faso, Senegal, and Niger are shown to differ markedly.

Transmission

Seed and Sap Transmission

Pecluviruses can be transmitted by sap inoculation and through peanut seed. The transmission rate through the peanut seed depends on the cultivar, the mode of infection (up to 24% for plants infected through soil and up to 50% for plants infected through seed) and the age at which the plants are infected. IPCV is transmissible up to rates of <2% through the seeds of pearl millet, finger millet, foxtail millet, wheat, and maize. Pearl millet CV GGP-16 did not transmit IPCV through seed.

Soil-Borne Vector Transmission

Both PCV and IPCV are naturally vectored by soil-borne protists, *P. graminis* (Fig. 1(e) and (f)). Two formae speciales of this species are associated with the transmission of PCV and IPCV: *P. graminis* f. sp. *subtropicalis* and *P. graminis* f. sp. *tropicalis*. These obligate root endoparasites complete their entire life cycle, including sporangial and sporogenic (resting spores) phases (Fig. 1(e) and (f); Fig. 3 right panel), only in monocotyledonous hosts in the family *Poaceae* (*P. graminis tropicalis* on sorghum, pearl millet, and maize but rarely on wheat and barley and *P. graminis subtropicalis* on sorghum, pearl millet, wheat, and barley). Nonetheless, they can infect and transmit viruses to dicotyledonous hosts, including peanut, which are considered to be fortuitous hosts of the vector. The presence of *P. graminis* in infested soils can be identified by growing bait plants such as pearl millet, sorghum, or wheat on infested soils or by PCR. *In vitro* transmission studies under controlled conditions is complicated because of the obligate parasitic nature of *P. graminis* and consequent difficulties in maintaining the cultures of both the virus and the vector in the same hosts. Nevertheless, the acquisition and the transmission of PCV by the vector is demonstrated using certain hosts such as sugarcane (CV CP-89-2377) and *Sorghum arundinaceum* supporting abundant zoospore production and virus infection. Presence of *P. graminis* in roots can also be quantified by reverse transcription quantitative PCR (RT-qPCR). The P39 viral protein, encoded by RNA2 and expressed by leaky scanning of P23, is involved in the transmission by *P. graminis* based on its similarity with P75 protein encoded by RNA2 of *Beet necrotic yellow vein virus* (BNYVV).

Virion Morphology

The virions of IPCV (Fig. 3 left panel) and PCV are non-enveloped rigid straight rod shaped, 24 nm (IPCV) and 21 nm (PCV) in diameter with two predominant lengths of c. 250 and c. 180 nm. They have helical symmetry with a pitch of 2.6 nm and contain a single coat protein (CP) of 23 kDa.

Physical Properties

Virions sediment as two major components with S_{20w} of 183S and 224S. Buoyant density in CsCl is 1.32 g cm^{-3} and isoelectric point is pH 6.45. Thermal inactivation of virus infectivity occurs at 64°C . Virions are stable in frozen leaves.

Molecular Properties

Genome Structure and Expression Strategies

The genome of pecluviruses is bipartite, with two positive-sense, linear single-stranded RNAs (ssRNAs) (4% in weight). RNA1 is c. 5900 nt long and RNA2 is c. 4500 nt long. The PCV RNAs show little sequence identity with those of IPCV RNAs except for the 3' terminal 273 nt, which are conserved among the two RNAs. Both the RNAs have methylated cap structure (to be confirmed) at their 5' ends. The 3' ends of the RNAs have tRNA-like structure and are not polyadenylated. Both RNAs are flanked by untranslated regions (5'- or 3' UTR) or noncoding regions (5'- or 3' NCR). The genome organization and expression of the PCV is shown in the Fig. 4.

Coding Sequences

RNA1 contains two open reading frames (ORFs) that encode two proteins involved in viral RNA replication (P131 and P191, Fig. 4; Table 1). The proximal ORF encodes a 131 kDa polypeptide and P191 is a C-terminally extended form of P131 produced by translational readthrough of the UGA termination codon. The P15 ORF is downstream of the P191 ORF and separated from it by a noncoding region of about 60 nt. The polypeptides of 131 and 191 kDa contain NTP-binding methyl transferase, helicase and RNA-dependent RNA polymerase (RdRp) domains and are involved in the putative replication complex (Table 1). The 15 kDa polypeptide, a cysteine-rich protein (CRP) is translated from a sub-genomic RNA (Fig. 4). It is a suppressor of post-transcriptional gene silencing (PTGS). The P15 possesses four C-terminal proximal heptad repeats that can generate a coiled-coil interaction and is targeted to peroxisomes via a C-terminal Ser-Lys-Leu (SKL) motif. Such a motif is conserved among pecluviruses from both Africa and India. It has been demonstrated that a coiled-coil motif is necessary for the anti-PTGS activity of P15, but the peroxisomal localization signal is not, although it is required for efficient intercellular movement of the virus. P15 resembles CRPs of *Barley stripe mosaic virus* (BSMV), *Poa semilatifolia virus* (PSLV), and SBWMV. These proteins have been suggested to act as regulatory factor during virus replication as well as for long-distance movement and contribute to the virulence factor. RNA1 can replicate in the absence of RNA2 in protoplasts of tobacco BY-2 cells. However, both RNAs are required for infection and systemic invasion of plants. Experiments using enhanced 5' green fluorescent protein and 5'-bromouridine 5'-triphosphate labels have suggested that PCV replication complexes co-localize with endoplasmic reticulum (ER) bodies accumulating around

Fig. 4 Genome organization of PCV (genus *Pecluvirus*, family *Virgaviridae*). The tRNA structure motifs at the 3' termini of the RNAs are represented by a dark square. ORFs are indicated by rectangles and a suppressible termination codon (UGA) by an arrow. Mtr, methyl transferase; Hel, helicase; RdRp, RNA-dependent RNA polymerase; CRP, cysteine-rich protein; CP, coat protein; TGB, triple gene block. Modified from Adams, M.J., Adkins, S., Bragard, C., *et al.*, 2017. ICTV virus taxonomy profile: Virgaviridae. Journal of General Virology 98, 1999–2000.

Table 1 Pecluvirus open reading frames (ORFs), polypeptides and their functions

Genomic RNA	ORF	<i>M_r</i> of polypeptide (kDa)	Function
RNA1	P131	131	Methyltransferase, helicase, replicase
	P191	191	
	P15	15	Suppressor of PTGS
RNA2	P23	23	Coat Protein
	P39	39	Putative vector transmission factor
	P51	51	Virus movement (triple gene block)
	P14	14	
	P17	17	

the nucleus during infection. P15 does not act directly at sites of viral replication but intervenes indirectly to control viral accumulation levels.

RNA2 contains five ORFs (Fig. 4). The 5' proximal ORF (23 kDa) encodes the CP, and the adjacent ORF (ORF2) encodes a 39 kDa polypeptide which is expressed by leaky scanning mechanism *in vitro* and thought to be involved in the transmission of PCV by its vector. ORF2 starts 1 nt upstream of the first residue of UGA stop codon of the CP cistron. Further, downstream and separated by 135 nt intergenic region, is a triple gene block (TGB) that codes for proteins of 51, 14, and 17 kDa that are presumed to be involved in the cell to cell movement.

5' and 3' Noncoding Sequences

The 5' and 3' NCRs of RNA1 of pecluviruses are about 130 and 300 nt in length, respectively (Fig. 4), whereas the RNA2 has more diverse NCR of 390–500 nt at 5' end and c. 300 nt at 3' end. Within the 3' NCR of RNA2, approximately 100 terminal nt are conserved among pecluvirus RNAs sequenced so far. The NCRs differ in size among isolates from the different serotypes. The 3' NCR of pecluviruses, as in the case of furoviruses, forms a t-RNA-like structure (TLS) that aids in the replication of both RNAs.

Fig. 5 (a) Phylogenetic tree constructed using coat protein (CP-P23) amino acid sequences from eight PCV/IPC isolates. (b) Phylogenetic tree constructed using 18 sequences of the 3' UTR of RNA1 and RNA2 of PCV/IPC isolates. The evolutionary distances were computed using Maximum Composite Likelihood method by Tamura, K., Dudley, J., Nei, M. Kumar, S., 2007. MEGA4: Molecular Evolutionary Genetics Analysis (MEGA) software version 4.0. Molecular Biology and Evolution 24, 1596-1599. GenBank Accession numbers are given in parentheses.

Sequence Comparisons and Phylogeny

Only one complete RNA1 genome sequence of each of PCV (X78602) and IPCV (X99149) are available, while five and three complete RNA2 sequences of PCV (L07269, AF447401, AF447400, AF447399, AF447398), and IPCV (AF447397, AF239729, AF447396), respectively are available in the database.

PCV and IPCV exhibited considerable differences in homology depending on the part of the genome sequence compared. The complete nt sequence of RNA1 of PCV is 78% similar to that of IPCV. The RNA1-encoded polypeptides (P191, P131, and P15) of PCV and IPCV share identities ranging from 75% (P15) to 95% (read-through portion of P191) and show significant similarities with furoviruses (e.g., 56% identity with polymerase of SBWMV). Comparison of the P15 gene shows a close relationship between IPCV isolates and a relatively high diversity among PCV isolates. The full-length sequence comparisons between RNA2 of PCV and IPCV isolates revealed a high degree of variability in size (between 58%–79%) and the proteins encoded by RNA2 are 39%–89% identical between species. Among the five ORFs of RNA2, ORF4 encoding P14 of TGB is highly conserved (90%–98%), whereas ORF2 encoded P39 is less conserved (25%–60%). Phylogenetic comparisons, based on complete RNA2 sequences, showed that the eight isolates could be grouped into three distinct clusters with no geographical distinction between PCV and IPCV isolates. Phylogenetic analysis of individual ORFs revealed an overall similarity with that obtained from complete RNA2 sequences, but the relative positions of individual isolates varied within each cluster. These studies indicate that there is substantial divergence among the RNA2's of pecluviruses and suggest that different polypeptides have evolved differently, possibly due to different selection pressures.

In the most members of the family *Virgaviridae*, CP is conserved among the isolates, but in the case of PCV and IPCV isolates, coat proteins are highly diverse (aa sequence identities between 37% and 89%) and have c. 30% similarity with the CP of BSMV (genus *Hordeivirus*). A conserved motif 'F-E-X₆-W' is present near the CP C-terminus of all three IPCV serotypes and PCV, as in the CPs of other rod-shaped viruses [*Tobacco mosaic virus* (TMV) and *Tobacco rattle virus* (TRV)]. Phylogenetic analysis of CP of eight PCV and IPCV isolates (PCV-B, PCV-M, PCV-N, PCV-Ni, PCV-S, IPCV-D, IPCV-H, IPCV-L) revealed that the PCV isolates grouped into two major clusters and IPCV into one cluster (Fig. 5(a)). The TGB proteins resemble those of *Potato mop top virus* (PMTV, genus *Pomovirus*).

Comparison of 3' end nt sequences revealed that they are highly conserved (88% for RNA1 and 85% for RNA2), thus offering a potential target for broad-spectrum detection by RT-PCR. Conservation of 3' UTR is verified by the alignment of eighteen 3' UTR (124 nt long) sequences of RNA1 and RNA2 (collected from NCBI database) of PCV/IPC isolates from different geographical regions and a phylogenetic tree has been constructed using the neighbor-joining method (Fig. 5(b)). The isolates were grouped into one Indian and two African clusters. Indian cluster appeared to be intermediate between the African clusters. Though there is high percentage of identity between 3' UTR of RNA1 and RNA2 of PCV and IPCV isolates from different geographical regions, there is no evidence of reassortment between isolates. Putative recombination events and their frequencies in the complete genome of 168 accessions extracted from the International databases representing several members of six genera Viz. *Furovirus*, *Pecluvirus*, *Comovirus*, *Tobravirus*, *Hardeivirus*, and *Tobamovirus* indicate that exchange of heredity material occurred between non-homologous sequences like those of IPCV and PCV.

Assembly of Virus Particles

Sequences required for assembly of PCV virions have been established by testing the ability of encapsidation of deletion mutants of RNA1 and RNA2 *in vivo*. A putative origin of assembly (OAS) is mapped in the 5' proximal part of the P15 gene of RNA1. Two sequence positions, 5' proximal CP gene and the other in the p14 gene near the RNA2 3' terminus that can drive encapsidation of RNA2, have been identified. No obvious sequence similarities between different assembly initiation sequences are noted.

The possible localization of an OAS in the CP gene of IPCV is realized as a result of the formation of virus-like particles (VLPs) in *Escherichia coli* and *N. benthamiana*, confirming the results observed for PCV. The monomer VLP size corresponded to the length of the encapsidated CP gene transcript RNA. Using immunocapture RT-PCR (IC-RT-PCR), such VLPs have been demonstrated to contain RNA encoding IPCV-H CP. Transgenic *N. benthamiana* expressing IPCV-H CP gene inoculated with the serologically distinct IPCV-L serotype accumulated virus particles that contained both types of CP, indicating that hetero-encapsidation occurs in transgenic plants.

Detection and Diagnosis

Pecluvirus diseased peanut plants occur in patches, mostly restricted to sandy/sandy-loam soils. The diseased peanut plants are stunted and dark green in color with or without chlorotic symptoms on leaves. Pecluvirus affected cereal and millet plants and grass weeds are difficult to recognize because they show mild or no visible symptoms. Diseases caused by pecluviruses reappear nearly in the same location year after year.

Immunoassays

Several immunological tests utilizing polyclonal (pAbs) and monoclonal antibodies (mAbs) have been used for the detection and identification of pecluvirus isolates. This approach revealed a diversity of serotypes and serogroups in Africa and India. The pAbs of PCV did not react with IPCV, BSMV, TMV, BNYVV, SBWMV, and PMTV. Wide serological diversity exists among PCV and IPCV isolates. Thus, serological tests have limitations to detect more than one isolate from a single antibody source. Antisera to different isolates of IPCV facilitated the grouping of isolates into three serotypes, IPCV-H (Hyderabad), IPCV-D (Durgapura), and IPCV-L (Ludhiana). All IPCV isolates are serologically distinct from PCV isolates and vice-versa. Utilizing a panel of mAbs raised against a PCV isolate and four different ELISA formats, several PCV isolates are grouped into five serotypes. Surprisingly, one of the mAbs reacted with IPCV-D in triple antibody sandwich ELISA. ISEM and alkaline phosphate or penicillinase-based ELISA formats have been applied for detection of both PCV and IPCV in various investigations.

Molecular Assays

It is essential to employ diagnostic tests that are highly sensitive and broadly specific for the detection of pecluviruses in disease surveys, to eliminate virus-contaminated sources in quarantine, and to devise strategies for disease control.

A broad-spectrum RT-PCR protocol, based on the conserved sequences of the 3' end region of genomic and sub-genomic RNAs of several virus isolates, has been developed to detect all the currently known IPCV and PCV isolates in various plant samples originated from different countries. Primers are also designed for quantitation of pecluvirus isolates using a TaqMan-based real time RT-PCR (RT-qPCR). RT-PCR is compared with penicillinase-based DAS-ELISA for the detection of pecluvirus isolates in crop and weed plants. The virus is detected in 70% of suspected plants by RT-PCR as compared to 24% detected by DAS-ELISA. The RT-PCR enabled the detection of virus in the plants that did not exhibit overt symptoms. The detection and quantification of PCV and IPCV isolates (IPCV-L, IPCV-H, IPCV-D, PCV-B, PCV-M, PCV-N, PCV-S) is performed by RT-qPCR. These PCR-based techniques are very useful for detecting PCV and IPCV especially in non-symptomatic hosts. RT-qPCR is recognized as an indispensable tool for tracing resistant cultivars and for the maintenance of pecluvirus-free germplasm. Immunocapture RT-PCR has also been used to demonstrate the presence of RNA in PCV VLPs.

Vector

Separation of *P. graminis* resting spores from sorghum root material facilitated pAbs production. In DAC-ELISA, they detected one sporosorus per well of the ELISA plate. In spiked root samples, the procedure detected one sporosorus per mg of dried sorghum roots. The majority of *P. graminis* isolates from Europe, North America, and India reacted strongly with pAbs. However, *P. graminis* isolates from Rajasthan state (North India), from Pakistan, and an isolate from Senegal (West Africa) reacted weakly with pAbs. The DAC-ELISA procedure is applied to detect various stages in the life cycle of *P. graminis* and to detect infection that occurs under natural and controlled environments. Resting spores are detected in root sections by using fluorescein 5-isothiocyanate - labeled pAbs.

Probes specific for nuclear ribosomal DNA (rDNA) detected the presence of *P. graminis* f. sp. *subtropicalis*, *tropicalis*, and *temperata* in roots by RT-PCR. *P. graminis* f. sp. *tropicalis* is quantified in plants inoculated with viruliferous zoospores using a specific RT-qPCR. The ribotypes of *P. graminis* f. sp. *temperata* and *P. graminis* f. sp. *tepida* are identified by restriction fragment length polymorphism analysis of PCR amplified rDNA, nested and multiplex PCR.

Fig. 6 Disease development cycle of Pecluviruses showing ways of acquisition, multiplication, and transmission by *Polymyxa graminis* through a variety of host plants. Modified from Delfosse P., 2000. Epidemiology and Management of the Indian peanut clump virus. Louvain-la-Neuve, Belgium: Université catholique de Louvain, PhD Thesis. Dieryck, B., Otto, G., Doucet, D., *et al.*, 2009. Seed, soil and vegetative transmission contribute to the spread of pecluviruses in West Africa and the Indian sub-continent. *Virus Research* 141, 184–189. Seed transmission data from Reddy, A.S., Hobbs, H.A., Delfosse, P., Murthy, A.K., Reddy, D.V.R., 1998. Seed transmission of Indian peanut clump virus (IPCV) in peanut and millets. *Plant Disease* 82, 343–346.

Epidemiology and Disease Cycle

The study of epidemiology and formulation of cost-effective disease control practices depend on the precise and sensitive detection of PCV and IPCV and their vector in plants, seeds, and soil. Peanut clump disease is largely confined to sandy soils and loams. Detection is required to identify infested fields, to select virus-free seed lots and vegetative propagules, to identify alternate hosts, and to assess the resistance of peanut, sugarcane and cereal and millet crops breeding lines.

Disease Development Cycle

The presence of viruliferous *P. graminis* vector, adequate soil moisture to facilitate the mobility of the vector zoospores from plant-to-plant in the sandy and sandy-loam fields, the optimum temperatures conducive to vector transmission and planting with seeds of virus-infected cereal crops contribute to primary spread. Presence of cereal hosts, ambient temperatures near 30°C and adequate moisture are vital for secondary spread. The relative contributions of favorable hosts for both the pecluvirus and its vector in the disease cycle are summarized (Fig. 6).

Dicotyledonous hosts limit the multiplication of the plasmodiophorid vector and hence considered them as fortuitous hosts that may not contribute to the perpetuation of the virus inoculum. Indeed, virus-infected peanut roots could not transmit or establish the disease. Monocotyledonous plants such as maize, sorghum, and pearl millet are 'preferred' hosts of the vector and contribute to the build-up of vector population potential in the soil. Seed of millets, maize and wheat, rhizomatous grasses (e.g., *C. dactylon*) and sugarcane vegetative propagules are likely to contribute to the disease establishment in new areas by supporting

the multiplication of the virus and vector. Soils from disease infested areas containing roots/rhizomes harbor resting spores of the vector. Dispersal of such infested soils by wind and displacement during tillering and plowing can contribute to the establishment of the disease in disease-free areas. During the rainy season, prolonged dry spells followed by supplementary irrigation in peanut fields may also contribute to the dispersal of resting spores and disease spread.

Disease Control

Research during the past four decades has led to the accumulation of considerable information on IPCV and PCV. It is now apparent that pecluviruses are not the viruses of peanut but should be regarded as viruses of cereals that opportunistically infect peanut. The difficulty in controlling such viruses is that they are both seed (in peanut, finger millet, foxtail millet, pearl millet, maize, wheat) and soil transmitted (through thick walled resting spores of the vector embedded in roots/rhizomes) and can also be propagated through sugarcane stem cuttings or the rhizomes of grass weeds. Continuous monocropping with fortuitous hosts such as peanut, bambara groundnut and pigeon pea will contribute to a reduction in plasmodiophorid population in soil. Seeds from infected cereal hosts should be avoided for planting. Thus, understanding precisely the sources of virus and vector and transmission mechanisms for each type of host plant in virus endemic agro-ecosystems using sensitive and specific diagnostic tools may lead to formulation of effective disease control practices.

Initial experiments with IPCV in India showed that application of soil biocides, e.g., DD (a mixture of 1,3-dichloropropene and 1,2-dichloropropane), fumigant nematicides that also have fungicidal action and soil solarization are effective on a limited scale in decreasing the disease incidence in peanut fields. Clump affected peanut plants always occur in patches and easy to avoid. Additionally, under field conditions early infected, which is the case, hardly produce any seed.

Cultural Practices

The following crop cultural practices are suggested for reducing disease incidence:

- Early planting of peanut, before the onset of monsoons under judicious irrigation.
- Planting with trap crops such as pearl millet at a high density, plowing of two-week-old seedlings into the soil followed by planting with peanut seed.
- Avoid crop rotation and intercropping with cereal and millet crops.
- Adopt continuous cropping with dicotyledonous crops (peanut, bambara groundnut, cowpea, pigeon pea) for at least three successive growing seasons.

Host Plant Genetic Resistance

No resistance to IPCV is found in over 9000 cultivated *Arachis* germplasm. Unfortunately attempts to incorporate resistance to IPCV by genetic engineering, deploying CP gene, have not produced successful results. However, cultivation with cereal hosts that did not show any seed transmission may help in limiting the disease establishment at *hitherto* disease-free locations.

Future Perspectives

At present the geographical distribution of pecluviruses is restricted to the Indian subcontinent and West Africa. Locations where peanut crops are grown in rotation or as mixed crops with cereal crops on sandy soils can be regarded as targets for establishment of clump disease. Hence measures must be taken to avoid planting with seeds from cereal crops resourced from clump infested fields. They also should not be used towards germplasm exchange because they pose a quarantine risk of introduction of pecluviruses into new geographical regions. Mapping of locations with peanut crops grown in sandy soils in rotation with cereal crops and peanut crops intercropped with cereals, along with the temperature range required for infection, should help in determining the potential for occurrence of pecluviruses in new locations.

RNA interference (RNAi)-mediated resistance has been found to be highly effective in controlling RNA virus infections, and such approach needs to be exploited to produce pecluvirus-resistant crops. The suspected role of P39 in vector transmission of the pecluvirus needs to be confirmed by mutational analysis in order to deploy this ORF in transgenic research. The presence of sub-genomic RNAs encoding P14 and P17 in infected tissues needs to be verified. The cultural control measures tested for IPCV are worth exploiting in West Africa to minimize the impact of PCV. Development of duplex or multiplex RT-PCR is necessary to distinguish peanut clump and groundnut green rosette diseases that visually look alike. Broadly specific nonradioactive probes must be made available to researchers in Africa and India.

Glossary

Double antibody sandwich - Enzyme-Linked-Immuno-Sorbent-Assay An assay in which by the use of a virus-specific antibody the presence of a virus in plants or plant parts can be established.

Immuno-sorbent electron microscopy Identification of a virus by visualization in the electron microscope of the reaction of the virus coat protein with a specific antiserum.

Reverse transcriptase polymerase chain reaction A PCR reaction whereby first a cDNA copy of the viral RNA has to be generated by Reverse Transcriptase (RT) before PCR-amplification is possible.

Virus symptomatology Typical local or systemic symptoms on natural host plants or experimental test plants that can be used to characterize and differentiate plant viruses and plant virus strains.

Introduction

Pepino mosaic virus (PepMV) was first found in 1974 in field samples of pepino plants (*Solanum muricatum*) located near some potato fields, collected in the Canete valley in coastal Peru. These plants showed some yellow mosaic in young leaves. Electron microscope (EM) investigations showed the presence of typical filamentous potexvirus particles of approximately 500 nm, which did not react with antisera against Potato virus X (PVX). Serologically it appeared most closely related to Narcissus mosaic virus (NaMV) but the host ranges from both viruses differ considerably. It was concluded that Pepino mosaic virus was a new and distinct potexvirus species.

Since its first description in 1980 the virus was never reported and not considered to be of any agricultural significance until it was described in 1999 from commercial protected tomato crops (*S. lycopersicum*) in the UK and The Netherlands. Since then the virus has spread very rapidly through commercial tomato crops and is now reported worldwide (See Relevant Websites Section). It is particularly present in Europe and The America's. In Africa and Asia its presence appears to be restricted and it has not been reported from Australia or New Zealand.

Taxonomy and Classification

Pepino mosaic virus is a species member of the genus *Potexvirus* within the family *Alphaflexiviridae*.

Virion Properties

PepMV has typical filamentous potexvirus particles with a normal length of 510 nm. Particles are comprised of a single capsid protein (CP) of approximately 26 kDa. Ultrathin section of infected leaf material may contain inclusions consisting of arrays of filamentous virus-like particles. The virus particles are less clearly cross-banded as those of PVX.

As a member of the genus *Potexvirus*, PepMV is fairly stable. In endpoint dilution studies, sap from infected *N. glutinosa* was always infectious at dilutions of 10^{-4} , occasionally at 10^{-5} but never at 10^{-6} . Sap lost most of its infectivity after 10 min at 65°C and was no longer infectious at 70°C. Sap stored at 20°C still shows some infectivity after 3 months while leaves of *N. glutinosa* desiccated over silica gel were still infectious after 6 months. Under practical conditions in greenhouses and fields the virus may

Fig. 1 Schematic organization of the RNA genome of Pepino mosaic virus with its five open reading frames (ORFs). M7G = 5' cap, AAAAA_n = poly-A tail.

easily survive for several weeks in plant debris and on surfaces (e.g., tools, clothes, containers) that have come in contact with virus-infected leaves or fruits.

Genome Organization and Expression

The genome of PepMV resembles that of typical potexviruses. For all strains its positive single-stranded RNA is around 6410 nt long, capped at the 5'-end, polyadenylated at the 3'-end and contains 5'- and 3'-untranslated regions. It encodes five putative partly overlapping open reading frames (ORFs 1–5, see Fig. 1). The following data are based on the RNA sequence of the original EU-tomato isolate PD99901066 (FJ940223) as found in 1999 in The Netherlands. Positions for regions and motifs in other isolates and other strains may vary slightly.

The 5'-untranslated region (5'-UTR) of the virus is 86 nt long and like all other potexviruses it starts with the 5'-GAAAA pentanucleotide.

ORF1 (nt 86–4406) encodes a 164 kDa protein of 1439 aa. It contains a putative methyl-transferase domain (MET; aa 59–224) specific for the supergroup of 'Sindbis-like' viruses, a NTPase/helicase domain (HEL; aa 708–934) with the NTP-binding motifs GCGGSGKS and VVIFDD and a RNA dependent RNA polymerase (RdRp) domain (aa 1217–1374) characterized by the SGEPTFDANT-X22-GDD motif.

The stop codon of the first ORF is followed by a short intergenic region (**IR1**) of 25 nt and a set of three partially overlapping ORFs typically known as the triple gene block (TGB).

ORF2 (nt 4432–5136) encodes the first Triple Gene Block protein (TGB1), a 234 aa protein of 26 kDa. This protein contains a typical NTPase/helicase motif (aa 26–233) characterized by 7 conserved motifs, two of which may be involved in NTP binding. TGBp1 belongs to the superfamily I of RNA helicases.

ORF3 (nt 5117–5488) overlaps 19 nt with the 3'-end of ORF2 and extends 148 nt past the start codon of ORF4. It encodes the TGB2 protein, a small 14 kDa protein which contains a potexvirus specific consensus motif: PxxGDxxHxL/FPxGGxYxDGTXxxxY.

ORF4 (nt 5340–5594) encodes the third TGB protein (TGB3), a 85 aa protein of 9 kDa. This protein is the most variable among potexviruses. It contains a CxV/lxxxG consensus motif among potexvirus TGB3 proteins. Substitution of Lysine (K) for glutamic acid (E) at position 67 in TGB3 was described as being involved in increased virus accumulation and the induction of systemic necrosis both in tomato and test plants. The TGB proteins are essential for virus movement, suppression of RNA silencing and the formation of the virus factory.

The second intergenic region (**IR2**) of 38 nt (nt 5595–5632) precedes **ORF5** (nt 5633–6346) which encodes the 238 aa coat protein (CP) of 25 kDa. This CP contains the amphipathic core sequence KFAAFDFFDGV. A similar sequence is also found in the CP of other potexviruses and might be responsible for binding of virus RNA to the CP through hydrophobic interactions. The PepMV CP is also required for cell-to-cell and long-distance movement and is involved in the suppression of RNA silencing.

The 64 nt long 3'-untranslated region (3'-UTR: nt 6347–6410) precedes the poly-A tail and contains the hexamer 5'-ACUAAA sequence which is also present in the 3'-UTR of all potexviruses sequenced so far. This motif is proposed to be a cis-acting element involved in the positive and negative viral RNA synthesis. The 5'-AAUAAA polyadenylation signal terminates the RNA genome whereby the AAA portion form the first A residues of the poly(A) tail.

Host Range and Symptomatology

The host range of PepMV is relatively broad infecting plants from different families including both cultivated and wild hosts. PepMV has not been reported to infect plants from the *Cucurbitaceae* or *Fabaceae*. Most plant species belong to the *Solanaceae* of which many species are infected systemically. Its main hosts appear to be *Solanum* spp. The originally described pepino strain was found to infect wild and commercial tuber-bearing *S. tuberosum* sp. (potato), mostly with a symptomless systemic infection or with mild mosaic symptoms but in two local Peruvian *S. tuberosum* cultivars and *S. stoloniferum* PI 230557 it caused a severe systemic necrosis. The virus was shown to be transmitted through the tubers.

Its best-known natural hosts are pepino (*S. muricatum*) and cultivated tomato (*S. lycopersicum*) but surveys showed infection with PepMV of several related wild *Solanum* spp. These include *S. peruvianum*, *S. parviflorum*, *S. chilense*, *S. chmielewskii*, and *S. pimpinellifolium*. Infections in these wild species were generally symptomless.

PepMV was also reported to infect other solanaceous crop and test plants; *Solanum melongena* (eggplant), *S. nigrum*, *S. tuberosum* (potato), *Datura stramonium*, *D. metel*, *D. innoxia*, *Nicotiana bethaminana*, *N. occidentalis*, *N. glutinosa*, and *N. tabacum* cv Xanthi. Sweet

pepper (*Capsicum annuum*) does not seem a suitable host since most PepMV strains were not able to induce a systemic infection, with the exception of the US1 strain which could induced systemic necrotic lesions.

Several weed hosts from various plant families (e.g., Convolvulaceae, Brassicaceae, Boraginaceae, Asteraceae, Plantaginaceae and Polygonaceae) were found to be hosts for PepMV. The original virus description reports weed hosts in Peru including *Datura stramonium*, *Nicandra physaloides* and *Physalis peruvianum*. Studies on sampled material from mainland Spain and the Canary Islands show a large number of weeds species latently infected (i.e., showing no symptoms)).

The initially described PepMV strain caused a distinct yellow mosaic on young leaves of pepino and most infected plant also showed dark green enations on the lower surface of some leaves. In *Solanum* spp. it caused a symptom less systemic infection as shown by back-inoculation on a sensitive indicator plants like *N. glutinosa*. Only *D. metel*, *D. stramonium*, and a number of *Nicotiana* sp. showed distinct symptoms upon systemic infection.

In contrast to the original Pepino isolate the EU-tomato virus isolate found in 1999 in commercial tomato crops in the UK and The Netherlands did cause distinct although generally mild symptoms in commercial tomato crops. In general, PepMV symptoms depend on the particular virus isolate in combination with the tomato cultivar, the age of the plant when first infected and environmental conditions. Symptoms may include small yellow leaf spots, yellow-green mosaic, mottle on the older leaves and/or slight curling in the top leaves (nettle-head symptom) or a greyish appearance of the top of the plant. Fruit symptoms may range from discoloration in the form of blotchy ripening or flaming, fruit marbling, mild sometimes concentric yellow/orange mottling and uneven ripening to netting and cracking ('open fruits') and shape distortion.

Basically, severity of symptoms in tomato may vary with the particular virus isolate involved. Both mild and severe symptoms inducing PepMV isolates have been described and there appears to be no correlation between symptom severity in tomato and the PepMV virus strain. Mild symptoms may vary from small yellow spots on leaves to a slight reduction in fruit production. Certain isolates can cause much more pronounced plant symptoms: more severe leaf chlorosis, bright yellow mosaic, leaf distortions ('bubbling'), green striation on the stem and sepals up to more or less pronounced leaf and stem necrosis. Because of fruit symptoms, fruit quality can be affected which may result in economic damage. Symptom expression is reported to depend on environmental conditions with low light conditions and low temperatures favouring more pronounced symptoms.

Inoculation studies of three PepMV strains (EU, CH2, and US1) clearly showed a number of differences between these strains on tomato and other solanaceous crops and test plants. Tomato is susceptible to all three strains, while sweet pepper (*C. annuum*) is generally not a systemically susceptible host for the three strains. Eggplant is susceptible to all three strains however local symptoms are seldom seen and systemic leaf symptoms may depend on locality and virus isolate. In potato systemic infections may develop in a sensitive cultivar but local and systemic symptoms are seldom seen. The virus however can infect the tubers and can thus be transmitted.

In test plants *N. occidentalis* 37B proved a useful susceptible host which is able to differentiate between strains based on typical local and systemic symptoms.

Virus Isolates and Strains

The first PepMV isolate was isolated in 1974 from pepino crops in Peru and only in 1999 an isolate was described on commercial tomato. Comparison of this tomato isolate with the original Peruvian pepino isolate (#BBA1137 in the DSMZ plant virus collection in Germany) showed some differences in a number of characteristics. These were most pronounced in the reactions of both isolates on tomato (*S. lycopersicum*) in which the pepino isolate is symptomless and the particular isolate of the tomato strain caused mild but distinct symptoms in the form of small sharp yellow flecks on leaves. Also on a number of test plants the two isolates can be distinguished, most clearly on *N. glutinosa* and *D. stramonium*.

Since 1999 a large number of different PepMV isolates have been described. These were either isolated from commercial tomato crops or tomato seed lots in different countries or from wild *Solanum* sp. Most show the typical characteristics of the tomato strain but some deviant isolates were observed. A number of isolates show more severe symptoms, (including leaf and stem necrosis and sever fruit symptoms) in tomato or wild *Solanum* sp. There is considerable biological variation between isolates and severity of symptoms is not related to the virus strain and in most strains both mild and severe isolates have been described.

Currently available biological data (i.e., host and indicator plant symptoms), serological relationships and multiple nucleotide sequence alignments (Fig. 2) suggest at least five clusters of relationship between the PepMV isolates which are now considered as separate genotypes or strains:

- (1) The Peruvian pepino strain (LP),
- (2) The European tomato strain (EU),
- (3) The Chile-2 strain (CH2),
- (4) The US1 strain (US1),
- (5) The PES strain, identified from wild *Solanum* species in Peru.

A significant number of full genome sequences are now available for PepMV with most sequences derived EU and CH2 isolates. Only a limited number of sequences from the LP, US1, and PES strains are published. Sequence identity between isolates of the same strain is high (i.e., above 98%) and several studies have shown that single strain populations of PepMV shown very low genetic variation over time. Direct full genome nucleotide sequence comparisons between strains showed that LP and EU strains

Fig. 2 Phylogenetic Maximum Likelihood tree of full-length RNA sequences of selected Pepino mosaic virus isolates of the five main strains. LP = Peruvian strain, EU = European tomato strain, CH2 = Chile-2 strain, US1 = US1 strain, PES = wild *Solanum* strain.

are most closely related with around 95% sequence identity. The US1 and PES strains share around 86% identity to each other and around 81% identity to the LP and EU strain. The CH2 strain is the most deviant as it generally shares around 78% sequence identity with the four other strains [Fig. 3](#).

Virus Transmission and Epidemiology

PepMV clearly originates from South America. Surveys in Peru showed that the virus was widespread, even in isolated wild *Solanum* sp., and phylogenetic analyses suggested that the virus most likely originated from a wild *Solanum* sp. Interestingly most infected *Solanum* sp. showed no distinct symptoms. Several studies have confirmed that the original Peruvian pepino isolate (LP) is characterized by the absence of, or only very mild symptoms on commercial tomato crops. The EU-strain isolate first found in 1999 in Europe also induces only mild symptoms in commercial tomato crops. This likely contributed to the initial rapid spread of the virus within and outside Europe.

Initial studies between 2000 and 2005 employing comparisons of viral gene sequences revealed that the tomato strain was prevalent in all countries reporting the virus. All tomato isolates found were all highly similar and could not be grouped according to geographic origin, or symptoms on naturally or experimentally infected plants. These data indicated a fairly recent introduction from limited sources and expansion of the tomato strain into commercial tomato crops, as the most likely cause for the virus epidemic.

Fig. 3 Symptoms of Pepino mosaic virus on tomato. A. Severe symptom on tomato plant. B. Detail of mild leaf symptom on tomato leaf. C. Severe symptom on tomato fruits. *Source:* Courtesy of R. van der Vlugt.

The first known occurrence of PepMV in North America can be traced back to 2000. Three strains were identified from pooled symptomatic leaf material collected in Arizona; US1, US2, and US3. US1 and US2 clearly differed from the EU and LP strains while US3 was highly homologous to the EU strain. Later studies revealed that US1 is indeed a distinct strain while US2 was a recombinant sequence between US1 and another strain now known as Chile-2 (CH2). US1 and CH2 were later confirmed as distinct strains on tomato seed originating from Chile.

In 2005 the CH2 strain was first found in commercial tomato crops in Europe and soon after that it started to spread rapidly, apparently because it seems to have a biological advantage over the EU strain in tomato.

Detailed population studies from Spain on material collected between 1998 and 2004 confirmed the prevalence and homogeneity of the tomato strain isolates as well as their presence since 1998. However, there were clear indications for several independent introductions of this virus strain, both on the Canary Islands and the Spanish Main land. Interestingly in addition to the tomato strain, also the original LP strain and the CH2 strain were found, but always in mixed infections with the tomato strain. Both strains were shown to be present in Spain since 2000.

Since 2005 the CH2 strain spread rapidly and is now the most prevalent strain in most commercial tomato crops where the virus is found however, it did not replace the EU tomato strain. Isolates for both strains can occur in mixed infections the same plant. The US1 strain is found only occasionally.

PepMV is a mechanically transmitted virus. The most important transmission routes are through contaminated tools, clothes, and surfaces. The virus is relatively stable at room temperature and can survive and stay infectious for several weeks in plant debris and on contaminated surfaces. Fruits from infected plants can contain high concentrations of virus and do not necessarily show symptoms. Long distance transmission of the virus in this way is relatively likely. Implementation of strict hygiene protocols during the growing season and thorough cleaning of greenhouses at the end of the growing season have shown to effectively control the introduction and spread of the virus.

PepMV is also transmitted by tomato seed at low levels whereby the virus is likely located on the seed coat. The virus was also shown to be efficiently transmitted between tomato plants in closed recirculating hydroponic systems as well as by bumblebees. The latter two transmission routes are likely to contribute to the spread of the virus in commercial closed greenhouse production systems whereby bumblebees are used for pollination.

The possible involvement of *Olpidium virulentus* in the transmission of PepMV has been reported as well as low levels of transmission from tomato to tomato under experimental conditions by the greenhouse whitefly (*Trialeurodes vaporariorum*) and the aphids *Myzus persicae*. Transmission of PepMV by these vectors remains to be confirmed.

Diagnostic

A polyclonal antiserum raised against the original pepino isolate shows no reaction with Potato virus X (PVX) and Potato aucuba mosaic virus (PAMV), the only two other potexviruses known to infect tomato. Both in immuno-sorbent electron microscopy (IEM) and in ELISA it clearly reacted with different tomato isolates. Comparisons of polyclonal antisera raised against the pepino and tomato strains showed differences in heterologous titres between them, but the antisera show clear reactions with isolates from all known PepMV strains.

Virus Damage and Control

Initially PepMV infections in commercial tomato crops were reported as relatively insignificant with no apparent plant or fruit symptoms and no or very limited yield reduction. Studies from the UK however, reported significant effects on fruit quality. Smaller sized fruits with different grades of uneven ripening and discoloration and occasionally mis-shaped fruits, led to production unsuited for the fresh UK market and hence economic damage.

Studies now clearly show that symptoms induction by PepMV is highly dependent on environmental conditions and on the particular isolate involved. In Spain, PepMV infected tomato plants showed only symptoms from autumn through spring and symptoms disappeared with higher temperatures in late spring. Similar effects of high light conditions and high temperatures have been reported from other countries. However, symptoms of PepMV infected plants can be highly variable, ranging from very mild leaf symptoms to severe leaf and stem necrosis. Fruit symptoms may vary from mild discolorations to open fruits showing severe cracking. Mild, chlorotic and even necrotic PepMV isolates have been reported and the capacity to induce different symptoms is a property of the isolate. There are indications that severity of symptoms may be associated with increased virus accumulation. Distinct single nucleotide mutations resulting in specific amino acid mutations in the viral CP and TGB3 genes were shown to be involved in the development of yellowing and necrotic symptoms, respectively. Also the highly conserved 'palm' domain in the Polymerase domain of the viral RdRp encoded by ORF1 of plays a role in the induction of plant necrosis which is apparently modulated by the interplay between the TGB3 protein, plant genotype and environmental conditions.

Currently no resistance genes to PepMV are available in commercial tomato cultivars. Extensive screening in wild *Solanum* sp. has been identified only a very limited number of potential resistance sources. Some accessions of *S. lycopersicoides* and *S. chilense* were resistant to isolates from the EU strain. Whether this resistance holds against the other PepMV strains remains to be investigated.

One method currently applied in various countries to control negative effects of PepMV infections is cross-protection i.e., the use of attenuated virus isolates. A mild isolate is inoculated onto plants in an early growth stage and the resulting systemic infection protects the plant against more severe isolates of the virus. Cross-protection is based on the sequence specific activation of the RNA-induced silencing complex (RISC). This general antiviral defense mechanism is sequence homology-dependent and is therefore not virus isolate- but strain-specific. Protection against severe EU-strain isolates requires an attenuated EU isolate while an attenuated CH2 isolate is required to protect against aggressive CH2 isolates. In many instances isolates of the CH2 and EU strains occur in mixed infections so for adequate protection mild isolates of both strains are required.

PepMV is a mechanically transmitted virus. The most important transmission routes are through contaminated tools, clothes and surfaces. The virus is relatively stable at room temperature and can survive and stay infectious for several weeks in plant debris and on contaminated surfaces. Fruits from infected plants can contain high concentrations of virus and do not necessarily show symptoms. Long distance transmission of the virus in this way is relatively likely. Implementation of strict hygiene protocols during the growing season and thorough cleaning of greenhouses at the end of the growing season have shown to effectively control the introduction and spread of the virus.

Effective control of the virus in commercial tomato culture should come from the use of virus-free seeds and planting material. For this reliable and sensitive methods, both serology and molecular based, for the detection of the virus in seed, plants and fruits are available. Since no adequate plant resistance is available yet strict hygiene measures and a constant monitoring for possible infections are required to avoid unwanted spread of the virus.

Glossary

Capsid The protein shell that surrounds a virus particle.

Cell-to-cell movement protein Virally encoded protein that helps viral virions or genome RNA (s)/protein complexes to move from cell to cell.

Dicotyledon A flowering plant that has two cotyledons in the seed.

Icosahedron Having 20 equal sides or faces.

Monocotyledon A flowering plant that has only one cotyledon, or seed leaf, in the seed.

RNA-dependent RNA polymerase Virally encoded RNA-dependent RNA polymerase that replicates viral genome(s).

Transovarial transmission Transmission from one generation to another through eggs.

Viral suppressor of RNA silencing Virally encoded protein(s) that suppress(es) host RNA silencing pathways.

Viroplasm Cytoplasmic, non-membranous structure in which plant reoviruses are thought to replicate and assemble.

Introduction

The family *Reoviridae* comprises a diverse group of viruses that can infect vertebrates, invertebrates, and plants. Despite their large host range, all members of the family *Reoviridae* share common properties, including an icosahedral-shaped virion and a segmented double-stranded RNA (dsRNA) genome. The family *Reoviridae* consists of 15 genera divided between two subfamilies, *Spinareovirinae* and *Sedoreovirinae*. Plant-infecting reoviruses are members of the genera *Oryzavirus* and *Fijivirus*, which belong to the *Spinareovirinae* subfamily, and the genus *Phytoreovirus*, part of the *Sedoreovirinae* subfamily. These reoviruses generally replicate both in their plant hosts and in their insect vectors. Infection of the insect vector is non-cytopathic and often persists throughout the life of the insect. Infection of the host plant is tissue specific (except for Rice dwarf virus [RDV]) and can cause severe disease. Fiji leaf gall disease, caused by Fiji disease virus (FDV), has caused yield losses of up to 90% in susceptible varieties of sugarcane in Australia. Rice ragged stunt virus (RRSV) is reported to reduce yield of rice by up to 100% in severe infections (although reductions of 10%–20% are more common). Rice common dwarf disease, caused by RDV, can also cause significant losses as infected plants often fail to set seed. Southern rice black-streaked dwarf disease, caused by Southern rice black-streaked dwarf virus (SRBSDV), was first discovered in Yangxi County, Guangdong Province, China, in 2001, and its distribution was limited to southern China until the end of 2008. By 2010, however, it had spread to 29 provinces of Vietnam and 13 provinces of China, and it has also now been found in some areas in Japan. The rapid spread of SRBSDV has caused serious rice losses in East and Southeast Asia.

Taxonomy and Classification

Currently, three genera of the family *Reoviridae* are classified as plant-infecting reoviruses: *Fijivirus*, *Oryzavirus*, and *Phytoreovirus*. The genera of plant-infecting reoviruses are differentiated according to the number of genomic dsRNA segments and their electrophoretic profile, hosts, serological relationships, and capsid morphology (Table 1). These reoviruses replicate both in plant hosts (except for one *fijivirus*: *Nilaparvata lugens reovirus*) and in their insect vectors (Table 1). Infection of the host plant is species specific, although the host range can often be extended under experimental conditions and can produce a variety of symptoms, including severe disease. None genome sequence information is now available for PaSV, GDV and ERSV. Partial genome sequence information is now available for WTV and OSDV. Complete genome sequence information have been obtained for all the other plant reoviruses. This has allowed detailed comparisons to be made within these genera and across all of the family *Reoviridae*,

Table 1 Characteristics of plant reoviruses

Subfamily, Genus Species name	Abbr.	dsRNA segments	Host	Vector (s)
Spinareovirinae Fijivirus				
Fiji disease virus	(FDV)	10	Gramineae	Planthoppers: <i>Perkinsiella saccharicida</i> , <i>P. vastatrix</i> , <i>P. vitiensis</i>
Rice black-streaked dwarf virus	(RBSDV)	10	Gramineae	Planthoppers: <i>Laodelphax striatellus</i> , <i>Ribautodelphax alba</i> fascia, <i>Unkanodes sapporona</i>
Maize rough dwarf virus	(MRDV)	10	Gramineae	Planthopper: <i>Ribautodelphax notabilis</i>
Pangola stunt virus	(PaSV)	10	Gramineae	Planthoppers: <i>Sogatella furcifera</i> , <i>S. kolophon</i>
Mal del Rio Cuarto virus	(MRCV)	10	Gramineae	Planthopper: <i>Delphacodes kuscheli</i>
Southern rice black-streaked dwarf virus	(SRBSDV)	10	Gramineae	Planthopper: <i>Sogatella furcifera</i>
Oat sterile dwarf virus	(OSDV)	10	Gramineae	Planthoppers: <i>Javesella pellucida</i> , <i>J. discolour</i> , <i>J. dubia</i> , <i>J. obscurella</i> , <i>Dicranotropis hamata</i>
Garlic dwarf virus	(GDV)	10	Liliaceae	Planthopper: Unknown
Nilaparvata lugens reovirus	(NLRV)	10	No plant host reported	Planthoppers: <i>Nilaparvata lugens</i> , <i>Laodelphax striatellus</i>
Spinareovirinae Oryzavirus				
Rice ragged stunt virus	(RRSV)	10	Gramineae	Planthopper: <i>Nilaparvata lugens</i>
Echinochloa ragged stunt virus	(ERSV)	10	Gramineae	Planthoppers: <i>Sogatella longifurcifera</i> and <i>S. vibix</i>
Spinareovirinae Phytoreovirus				
Wound tumor virus	(WTV)	12	Dicot	Leafhoppers: <i>Agallia constricta</i> , <i>A. quadripunctata</i> , <i>Agalliopsis novella</i>
Rice dwarf virus	(RDV)	12	Gramineae	Leafhoppers: <i>Nephotettix cincticeps</i> , <i>N. nigropictus</i> , <i>Recillia dorsalis</i>
Rice gall dwarf virus	(RGDV)	12	Gramineae	Leafhoppers: <i>Nephotettix cincticeps</i> , <i>N. nigropictus</i> , <i>N. virescens</i> , <i>N. malayanus</i> , <i>Recillia dorsalis</i>

providing a basis for their classification into species and genera. One general feature is the presence of inverted repeats several bases long adjacent to the conserved terminal sequences in all plant-infecting reoviruses; the sequences of the repeats differ among the three genera.

Within the genus *Fijivirus*, individual species have considerable similarities to FDV, the type species. Their classification into separate species is based on unique characteristics, such as capacity to exchange genome segments, relatively high aa sequence similarity, serological cross-reaction, cross-hybridization of RNA or cDNA probes, host species, and insect vector species. Analysis of the available genome sequences has further assisted the identification of *Fijivirus* species. The gross genome characteristics of fijiviruses includes a genome size of approximately 29 kbp and a characteristically low G + C content of 34%–36%. The 3' terminal trinucleotide in the positive strand is unique and highly conserved in all RNA segments among all species within the genus *Fijivirus* (Table 2). Members of the genera *Oryzavirus* and *Phytoreovirus* have significant similarity to their type species, RRSV and *Wound tumor virus* (WTV), respectively. Demarcation of species within the oryzaviruses and phytoreoviruses is primarily based on the ability to exchange genome segments although other characteristics, as mentioned for fijiviruses above, are also used. When available, genomic sequences are examined to reveal distinguishing features to support the classifications. Oryzaviruses have a total genome size of approximately 26 kbp and specific 5'- and 3' terminal sequences in all RNA segments, resulting in the canonical structure 5'GAUAAA–GUGC3'. Phytoreoviruses have a total genome size of approximately 25 kbp, a G + C content between 38% and 48%, and specific 5'- and 3'-terminal sequences in all RNA segments [canonical structure 5'GG(U/C)A–(U/C)GAU3'].

Virion Structure and Genome Organization

Fijivirus

Fijivirus virions have a complex double icosahedral capsid construction and consist of a capsid, a core, and a nucleoprotein complex. Virions are fragile structures and readily break down *in vitro* to give cores unless pretreated with fixative. The outer capsid is 65–70 nm in diameter with 12 “A”-type spikes located at the vertices of the icosahedron. The inner core is about 55 nm in diameter, with 12 “B”-type spikes located at the vertices. The viral nucleic acid is located at the center of the virus particle, within the inner core capsid (Fig. 1(A)). Each virion contains a single full-length copy of the genome. Fijivirus genomes contain 10 dsRNA genomic segments varying from approximately 1.8 to 4.5 kbp (Fig. 2). The total genome is approximately 29 kbp, with a low G + C content of 34%–36%. Within the genus, the only conserved sequence is found at the 3'-terminus (canonical structure ...GUC-3'; Table 2). Segment-specific inverted repeats are found adjacent to these terminal sequences. Segments 1–6, 8, and 10 are monocistronic, containing one open reading frame (ORF), while segments 7 and 9 each contain two ORFs, although the expression of the second ORF has not been certified *in vivo* in either plant cells or insect vectors. NLRV is the only fijivirus identified to date that differs from this standard structure, with only one ORF on segment 10, which is equivalent to segment

Table 2 Conserved terminal sequences (positive strand) in fijiviruses

Virus	5' conserved sequence	3' conserved sequence ^a
Fiji disease virus	5'-AAGUUUUU-3'	5'-CAGCNNNNGUC ^{3'}
Rice black-streaked dwarf virus	5'-AAGUUUUU-3'	5'-AGCUNN(C/U)GUC ^{3'}
Maize rough dwarf virus	5'-AAGUUUUUU-3'	5'-UGUC ^{3'}
Mal del Rio Cuarto virus	5'-AAGUUUUU-3'	5'-CAGCUNNNNGUC ^{3'}
Oat sterile dwarf virus	5'-AACGAAAAAA-3'	5'-UUUUUUUUUAGUC ^{3'}
Nilaparvata lugens reovirus	5'-AGU-3'	5'-GUUGUC ^{3'}
Southern rice black-streaked dwarf virus	5'-AAGUUUUU-3'	5'-CAGCUGAUGUC ^{3'}

^aItalicized trinucleotides are conserved in all fijivirus sequences reported to date.

Fig. 1 Diagrammatic representation of the particle structures of Fiji disease virus (A), Rice ragged stunt virus (B), and Rice dwarf virus (C).

Fig. 2 Genome organization of Fiji disease virus (FDV) containing 10 dsRNA segments. Each segment contains one ORF except for Seg 7 and Seg 9 which contain two ORFs. The green arrows indicate the conserved 5' terminal sequence (5'-AAGUUUUU-3') while the red arrows indicate the conserved 3' terminal sequence (5'-CAGCNNNNGUC^{3'}). The red segment encodes the RdRp. The green segments encode the structural proteins. The yellow segments encode non-structural proteins or proteins with unknown function.

7 of FDV. The functions of the proteins encoded by some of the ORFs are still unconfirmed; the functions of segments 1–3 and 7–10 have been predicted based on protein expression studies or deduced from those of the equivalent segments of other virus species within the genus (Table 3).

Oryzavirus

Oryzavirus virions have a double-shelled icosahedral capsid and consist of an outer capsid, an inner capsid, and a core. Virions are fragile and readily break down *in vitro* to give subviral core particles unless pretreated with fixative. The outer capsid is 75–80 nm in diameter with 12 “A”-type spikes located at the 5-fold axis of the icosahedron. The core capsid is about 57–65 nm in diameter,

Table 3 Genome organization of FDV and predicted gene function

Segment	Size (bp)	Protein nomenclature	Predicted MW (kDa)	Predicted function (location)
S1	4532	VP1	170.6	RdRp (core)
S2	3820	VP2	137.0	Major core (core)
S3	3623	VP3	135.5	Possible B spike (outer capsid)
S4	3568	VP4	133.2	Unknown
S5	3150	VP5	115.3	Unknown
S6	2831	VP6	96.8	Unknown
S7	2194	VP7a	41.7	Possible tubule protein (nonstructural)
		VP7b	36.7	Unknown
S8	1959	VP8	68.9	Possible NTP-binding (core)
S9	1843	VP9a	38.6	Structural protein (viroplasm)
		VP9b	23.8	Unknown
S10	1819	VP10	63.0	Outer capsid protein (major outer capsid)

Fig. 3 Genome organization of Rice ragged stunt virus (RRSV) containing 10 dsRNA segments. Each segment contains one ORF except for Seg 4 which contains two ORFs. The green arrows indicate the conserved 5' terminal sequence ($5'$ GAUAAA- $3'$) while the red arrows indicate the conserved 3' terminal sequence ($5'$ -GUGC $3'$). The red segment encodes the RdRp. The green segments encode the structural proteins. The yellow segments encode non-structural proteins or proteins with unknown function.

with 12 “B”-type spikes. The viral nucleic acid is located at the center of the viral particle, within the core capsid (**Fig. 1(B)**). The virus genome consists of 10 linear dsRNA segments ranging in size from 1162 to 3849 bp (RRSV) with a total length of 26 kbp (**Fig. 3**). Genome segments 1–3 and 5–10 of RRSV each contain a single ORF, while segment 4 contains two ORFs. Segment 8 encodes a polyprotein that is autocatalytically cleaved into at least two polypeptides. **Table 4** summarizes the organization of the RRSV dsRNA segments and the predicted function of the encoded proteins.

Phytoreovirus

Phytoreovirus virions have a double-shelled icosahedral capsid construction and consist of an outer capsid, a core capsid, and a smooth core. Virions are approximately 70 nm in diameter, with 12 spikes located at the 5-fold vertices of the icosahedron, and generally remain intact when purified. WTV, the type member, has three protein shells: an outer amorphous layer made up of two proteins, an inner capsid made up of two proteins, and a smooth core made up of three proteins that is about 50 nm in diameter (**Fig. 1(C)**). Each virion contains a single full-length copy of the genome. Phytoreoviruses have 12 segments of linear dsRNA ranging in size from approximately 1 to 4.5 kbp, with a total genome length of approximately 25 kbp (**Fig. 4**) and a G + C content of 41%–48%. Each segment of RDV contains a single ORF except for segments 11 and 12, which contains two ORFs. **Table 5** summarizes the organization of the RDV dsRNA segments and the putative function of the encoded proteins.

Table 4 Genome organization of RRSV and predicted gene function

Segment	Size (bp)	Protein nomenclature	Predicted MW (kDa)	Apparent MW (kDa)	Predicted function (location)
S1	3849	P1	137.7	137	Virion core associated (B spike)
S2	3810	P2	133.1	118	Inner core capsid, putative guanylyl-transferase (core capsid)
S3	3699	P3	130.8	130	Major core capsid (core capsid)
S4	3823	P4a	141.4	145	RdRp
		P4b	36.9		Unknown
S5	2682	P5	91.4	90	Capping enzyme
S6	2157	Pns6	65.6		Non-structural protein, VSR, cell-to-cell movement
S7	1938	Pns7	68	66	Non-structural protein, NTP-binding protein (unknown)
S8	1814	P8	67.3	67	Precursor polyprotein/protease
		P8a	25.6	47	Spike
		P8b	41.7	44	Major capsid protein
S9	1132	P9	38.6	37	Vector transmission, mild silencing suppressor activity (spike)
S10	1162	Pns10	32.3	32	Non-structural protein associating with a mitochondrial membrane component, oligomycin-sensitivity conferral protein (OSCP), to facilitate virus propagation in the vector

Fig. 4 Genome organization of Rice dwarf virus (RDV) containing 12 dsRNA segments. Each segment contains one ORF except for Seg 11 and Seg 12 which contain two ORFs. The green arrows indicate the conserved 5' terminal sequence ($5'$ GG(U/C)A- $3'$) while the red arrows indicate the conserved 3' terminal sequence ($3'$ -(U/C)GAU- $5'$). The red segment encodes the RdRp. The green segments encode the structural proteins while the yellow segments encode non-structural proteins.

Replication and Gene Expression

The replication and gene expression of plant-infecting reoviruses is thought to be similar to that of other reoviruses. The best described of these is *Bluetongue virus* (BTV), the type member of the genus *Orbivirus*. If the BTV model is accurate for the plant-infecting reoviruses, replication occurs after virions (or viral cores) are delivered into the host cell. Replication is initiated when the viral capsid layer is removed and the transcriptionally active core enters the cytoplasm. The viral genome (10–12 segments) remains packaged in the central cavity of the viral core to ensure that host cell defense responses to dsRNA are not activated. The core is biochemically active with an RNA-dependent RNA polymerase (RdRp), a capping enzyme, and a helicase. The viral core contains a number of channels, the largest of which is at the 5-fold axis of the icosahedral structure. Smaller channels allow the entry of nucleotides, which are required for transcription, into the core. The large channel is located adjacent to the replicase/transcriptase complex, which through its helicase activity executes the unwinding and rewinding of the dsRNA genome during transcription of the negative (antisense) RNA strand. The newly formed positive-strand (sense) mRNA molecules are modified to form a Cap 1 structure [7mGpppG^(2-Om)...] by the guanylyl-transferase, nucleotide phospho-hydrolase, and transmethylase

Table 5 Genome organization of RDV and gene function

Segment	Size (bp)	Protein nomenclature	MW ^a	Function (location)
S1	4423	P1	170	RdRp (core)
S2	3512	P2	130	Capsid structural protein, essential for vector transmission and symptom formation in plant host (outer capsid)
S3	3195	P3	110	Major core protein (core capsid)
S4	2468	Pns4	83	Phosphorylated nonstructural protein, associated with large cytoplasmic fibrils to form novel mini-tubules in infected cultured leafhopper cells, essential for viral infection in its insect vector (viroplasm, at the early stages of infection; amorphous or fibrillar inclusions, at the later stages of infection)
S5	2570	P5	89	Guanylyltransferase (core)
S6	1699	Pns6	56	Nonstructural protein, viroplasm matrix protein in insect vector cells, involved in cell-to-cell movement and nuclear acid binding in plant host
S7	1696	P7	58	RNA-binding protein (core)
S8	1427	P8	43	Major outer capsid protein
S9	1305	P9	49	Structural protein (outer capsid)
S10	1321	Pns10	35	Nonstructural protein, VSR in plant host, involved in intercellular transport in insect vector cells
S11	1067	Pns11a	23	Nonstructural protein, viroplasm matrix protein, involved in nuclear acid binding protein
		Pns11b	24	Non-structural protein, enhancing the enzymatic activity of rice S-adenosyl-L-methionine synthetase, triggering ethylene production in rice in order to achieve efficient infection

^aMW determined by SDS-PAGE (kDa).

activities of the capping enzyme and are then extruded through the major pore into the cytoplasm, where they can be translated to produce viral proteins. Non-structural viral proteins form viroplasm. The viroplasm is the site of most of the mRNA synthesis, genome replication, and assembly of core proteins. The various species of mRNAs synthesized in the viroplasm display in non-equimolar ratios. However, the dsRNA genome segments are usually packaged in exactly equimolar ratios (*i.e.*, one copy of each genome segment per particle), which indicates that the selection of viral mRNAs for packaging is highly specific; recognition signals on each mRNA species may be related to this process. Once a copy of an mRNA is inside a new viral core, the corresponding negative strand is synthesized, completing the replication of the dsRNA genome. The progeny viral core containing dsRNA then moves to the periphery of the viroplasm, where capsid proteins are assembled to form the complete new viral particle and are thought to stop further mRNA synthesis. Like the parental-virus-derived smooth cores (without a capsid layer), progeny viral cores also synthesize mRNAs, providing an amplification step during replication.

In recent years, researchers have proposed a new model for the genesis and maturation of viroplasms induced by SRBSDV in insect vector cells. The SRBSDV viroplasm consists of a granular matrix formed by the non-structural protein P9 and a filamentous matrix formed by the non-structural protein P5. The progeny viral cores and mature virions assemble in the filamentous matrix. The new viral mRNAs synthesized by the progeny viral cores and virions within the filamentous matrix are then transported to the granular matrix by association with SRBSDV non-structural protein P6. As a result, viral mRNAs accumulate in the granular matrix, and these viral mRNAs may either migrate to the adjacent cytoplasm to synthesize viral proteins that promote further maturation of viroplasms or migrate back to the filamentous viroplasm matrix and be packaged into empty core particles, which are assembled and aligned along the filaments within the filamentous matrix to form viral-RNA-containing core particles. The subsequent minus-strand RNA synthesis and outer capsid protein assembly processes also take place in the filamentous matrix, leading to the maturation of a new virion. Thus, the P9 formed granular matrix plays important roles in viral RNA and protein production and filamentous matrix maturation. Compared to the globular structures of phytoreovirus and oryzavirus viroplasms, the filamentous matrix of the fijivirus (SRBSDV) viroplasm gives it a much larger surface-area-to-volume ratio, which leads to produce more progeny virions in the insect vectors.

The control of gene expression for a multi-segmented genome is complex and not fully understood. Each genome segment contained within the viral core is associated with a single replicase/transcription complex, located adjacent to the major pore in the vertices of the icosahedron, and is transcribed separately to make full-length positive-strand RNA copies. The location of the replicase/transcription complex also restricts the number of genome segments to a maximum of 12. These 10–12 mRNAs are produced in different molar amounts based largely on segment size, resulting in more copies of the smaller mRNAs. The conserved 5'- and 3' terminal sequences of the RNA segments may function as recognition signals for the replicase/transcription complex and be involved in the efficient initiation of viral mRNAs translation, providing some control over the expression levels of individual virus genes. In addition, the conserved and non-hybridized 3'-terminal sequences have been shown to be required for efficient negative-strand synthesis. A third level of control

results from the presence of multiple or overlapping ORFs on one mRNA strand that are translated at different efficiencies. Lastly, some ORFs encode a polyprotein that must be processed to form functional proteins.

Distribution

Plant-infecting reoviruses are seasonally distributed as a result of plant host/crop cycles and abundance of insect vectors. They can overwinter in certain weed crops, in autumn-sown cereals, and in diapausing insect hosts. With SRBSDV, for example, the distribution of the virus is consistent with the migration and existing ranges of its main host vector, the white back planthopper (WBPH; *Sogatella furcifera*). In Southeast Asia, WBPH is a long-distance migratory rice pest. In most rice-growing areas in China, no winter rice is sown, with the exceptions being the southwestern province, Yunnan and Hainan. These two areas have therefore become the major WBPH overwintering regions in China. In early spring, viruliferous WBPH begin their migration northward with the help of the northeastward air flow, and by late June or early July, they can reach as far as Japan. As a result, viruliferous WBPH transmit the virus throughout its journey, in regions including Guangdong, Guangxi, Hunan, Jiangxi, and Fujian provinces in China. Moreover, viruliferous WBPH also lay eggs in the newly colonized areas, and the next generation of WBPH propagate on the infected rice seedlings, acquire viruses, become viruliferous, disperse, and induce new disease outbreaks. In the autumn, the viruliferous WBPHs then return to their ideal overwintering region, Yunnan and Hainan provinces, when the monsoon winds shift direction.

Plant reoviruses have been identified from every continent, but some genera are more widespread than others. Fijiviruses are the most widely distributed, which is not surprising given that they are the most numerous, although they are absent from North America and India. Fijiviruses have been reported to occur in Africa, Europe, South America, Asia, Australia, and the South Pacific Islands. Oryzaviruses have only been isolated from the Indian subcontinent and Asia, while phytoreoviruses have been isolated from North America, Asia, and Africa.

Host Range and Virus Transmission

Fijiviruses

The genus *Fijivirus* contains nine species whose members infect a range of monocotyledonous plants of the families *Gramineae* and *Liliaceae*. Common natural plant hosts include *Avena sativa*, *Oryza sativa*, *Saccharum officinarum*, and *Zea mays* among the *Gramineae* and *Allium sativum* among the *Liliaceae*, although this host range can be extended significantly by experimental virus infection. Viruses are transmitted by delphacid planthoppers (Table 1). Viruses can be acquired in juvenile plant growth stages, replicate in the vector, and, following a latent period of at most 2 weeks, are transmitted to plants in a persistent manner. No transovarial or seed transmission of viruses has been reported. In addition to transmission by insect vectors, mechanical transmission of the virus to susceptible hosts has been achieved for some fijiviruses with difficulty. In 2017, researchers reported a novel method for transmitting SRBSDV to rice, the bud-cutting method. With this approach, the 1.0-cm pregerminated rice bud was cut at a 45° angle approximately 0.5 cm from the base of the bud. The seedlings were then soaked in a crude SRBSDV extract obtained from SRBSDV-infected rice samples with a phosphate-buffered saline and then incubated in the dark at 28–30°C for 3 days. Lastly, the rice seedlings were planted in a soil matrix and incubated under growing conditions appropriate for rice. After 25 days, the rice seedlings displayed disease symptoms similar to those of rice seedlings infected with WBPH, and intact SRBSDV virions were isolated from the seedlings. The transmission efficiency with this method was more than 80%.

Oryzaviruses

The genus *Oryzavirus* contains two species whose members infect monocotyledonous plants of the family *Gramineae*. Common plant hosts include *O. sativa* and *Echinochloa crus-galli*. However, this natural host range can be extended by experimental virus infection to include other economically important species such as *Hordeum vulgare*, *Triticum aestivum*, and *Zea mays*. Virus is transmitted by delphacid planthoppers (Table 1). An acquisition period of 3 h is required followed by a 9-day latent period prior to transmission at all life stages in an intermittent manner. No transovarial transmission or mechanical transmission of virus has been reported.

Phytoreoviruses

The genus *Phytoreovirus* contains two species whose members infect monocotyledonous plants of the family *Gramineae* and one species that infects dicotyledonous plants. Common plant hosts include the *Gramineae* *O. sativa* and the dicot *Melilotus officinalis*. However, the natural host range of the dicot-infecting WTV can be extended significantly by experimental virus infection. Virus is transmitted by cicadellid leafhoppers (Table 1). Virus can be acquired after a short feeding period, replicates in the vector, and, following a 10- to 20-day latent period, is transmitted to plants throughout the life of the vector. Transovarial transmission of virus has been reported. Attempts to transmit the virus to susceptible hosts by mechanical methods have been unsuccessful.

Pathogenicity

The pathogenicity of plant reoviruses is particularly interesting as most viruses replicate in both insects and plant hosts. Most do not appear to cause any disease in the insect host, so that their pathogenicity is restricted to the plant host. The pathogenicity of fijiviruses varies considerably. Fiji leaf gall disease (caused by FDV) is reported to cause losses of up to 90% in susceptible sugarcane varieties, while NLRV has no known plant host and, therefore, no known pathogenicity. Oryzaviruses can also cause important yield losses. Rice ragged stunt disease (caused by RRSV) is reported to cause losses of generally 10%–20%, but sometimes as high as 100% in severe infections of susceptible varieties. The pathogenicity of phyto-reoviruses is much milder, although rice dwarf disease (caused by RDV) can have severe effects, as infected plants often fail to bear seeds. Furthermore, different strains of RDV–O, D84, and S–cause diseases of varying severity: RDV-S causes the severest symptoms and RDV-O the mildest.

Although many aspects of the molecular bases for pathogenicity remain opaque, we now know a small part of the processes leading to rice dwarf disease symptoms. As mentioned before, RDV-infected plants exhibit disease symptoms that include dwarfing, short crown root, and increased tiller number. Some researchers have found this phenomenon similar to the phenotype observed when plants lose their sensitivity to auxin signaling. After meticulous experimentation, researchers finally determined that the symptoms are caused by the RDV capsid protein P2, which disrupts interactions within the auxin coreceptor complex, leading to the plant's failing to perceive auxin. Besides this, viruses have evolved many other mechanisms to counteract plant antiviral strategies, most notably through the expression of viral suppressors of RNA silencing (VSRs). VSRs take advantage of RNA silencing and plant hormone pathways to destroy plant fortifications. As another example, the RDV nonstructural protein Pns11 can manipulate the plant ethylene biosynthesis process by enhancing the enzymatic activity of S-adenosyl-L-methionine synthetases, resulting in higher ethylene level in plants and making plants more susceptible to RDV infection. It is also has been demonstrated that RRSV infection mediates disease symptoms *via* suppression of jasmonic acid-associated antimicrobe signal through the microRNA319-TCP21 regulatory module.

Furthermore, the pathogenic effects of different plant-infecting reoviruses can influence each other. RRSV is widely distributed in Eastern and Southeastern Asia, but until recently had not caused serious crop losses in China owing to its low incidence. Lately, as SRBSDV has spread, RRSV has become more and more common in China and has been frequently found coinfecting plants with SRBSDV. Researchers propose that the recent increase in RRSV incidence in China is partially due to synergism between SRBSDV and RRSV because they have found that not only do rice plants coinfecting with both viruses exhibit higher virus titer and enhanced and earlier disease symptoms, but also the respective insect vectors of SRBSDV and RRSV acquired the viruses from the coinfecting plants at higher rates than from singly infected plants.

Diagnosis and Control

Diagnosis of plant reovirus infections can be done on the basis of disease symptoms or through the use of molecular tests. Symptoms vary between virus/host complexes but commonly include dark-green coloration, suppression of flowering, plant stunting, increased numbers of side shoots, and vein swelling or gall formation derived from phloem tissue on the backs of leaves. Given the variability in time to symptom expression and symptom severity, alternative tests are often used. Molecular and serological tests have been developed to assist in the diagnosis of viral infection in non-symptomatic plant material and vector insects. Serological tests are usually in enzyme-linked immunosorbent assay (ELISA) format and rely on polyclonal antisera raised against virions or expressed viral proteins. For example, antibodies against glutathione-S-transferase–NS7 fusion protein are useful in ELISAs for the detection of RRSV in infected plants and insect vectors, and a rapid, highly reliable, sensitive, and specific dot-format ELISA has been developed for SRBSDV detection using anti-SRBSDV rabbit antiserum. Recently, molecular tests such as reverse transcription–polymerase chain reaction (RT-PCR), which are faster and more specific than serology, have become the most common diagnostic methods. As increasing numbers of plant reovirus genomes are sequenced, species-specific primers are now becoming commonly available. A simple, rapid, sensitive, so-called multiple (m) RT-PCR method, which uses a mixed set of primers specific for *Rice stripe virus* (RSV), RBDSV, and SRBSDV together, can efficiently detect all three viruses simultaneously, and a one-step mRT-PCR assay has been established for simultaneous detection of RSV, RBDSV, and RDV. Meanwhile, a reverse transcription loop-mediated isothermal amplification (RT-LAMP) assay has been developed for the detection of RBDSV, RDV, RGDV, and RRSV, which can obtain a diagnosis within 2 h when combined with RNA rapid extraction.

Control strategies for plant reoviruses can be focused on either the host plant or the insect vector. Plant-based control through breeding to develop resistant plant species is most commonly utilized in combination with the removal of susceptible varieties and infected plants that provide a source of inoculum. This approach has provided robust control of RDV in rice and FDV in sugarcane. Genetic engineering of plant hosts has also been explored as an alternative control strategy. Pathogen-derived resistance approaches directed at either coat proteins or other viral genes to control RDV, RRSV, and FDV have proved less successful than those used to control other RNA plant viruses.

Control of insect vector populations with insecticide has provided some additional disease control. Unfortunately, chemical control appears to be of limited use in cases of high vector pressure. The current combination of diagnosis and control measures is already relatively effective and has resulted in reduced disease incidence and impact. Control measures based on protecting plants from WBPH, including seedbed coverage, chemical seed treatments, and chemical spraying of seedlings, have been demonstrated to be useful in controlling SRBSDV in China.

Despite breakthroughs over the years, such as the discovery that RDV can use actin-based tubule motility to overcome transmission barriers and exploit the ancient oocyte entry path of the bacterial symbiont in leafhopper, many gaps in our understanding of transmission mechanisms remain. However, this situation may improve in the future as advances in genome sequencing, reverse genetics systems, genome editing, and molecular technologies help provide more information on virus infection and replication and, thus, new resistance targets.

Future

Although our understanding of plant reoviruses is expanding, many of the molecular and biological properties of these viruses are still unknown. The complete sequence information now available for a number of these viruses will allow the production of cDNA probes to further elucidate the viral infection and replication processes in both plant and insect cells. The potential to produce infectious clones also holds promise for detailed studies of both plant and insect host ranges and of the methods of resistance employed by non-host species. This information, combined with knowledge gained from comparisons with animal reoviruses, may assist the further development of control strategies for diseases caused by these viruses in plants.

Glossary

Allele Allele is a distinct form of a gene at a particular locus, that shows different effect on the phenotype from the other forms of alleles.

Betasatellite A type of circular single-stranded satellite DNA associated with begomoviruses.

CRISPR-Cas The acronym for Clustered Regularly Interspaced Short Palindromic Repeat – CRISPR-associated protein, an adaptive immune system used by bacteria and archaea against viruses and mobile genetic elements, which has been adapted for genome editing in eukaryotes.

Dominant allele An allele expressing its phenotypic effect even when having a recessive allele as its counterpart in a heterozygous system.

NB-LRR protein Plant disease resistance proteins containing a central nucleotide-binding domain (NB) and C-terminal leucine-rich repeat (LRR) domain. Also known as NBS-LRR or NB-ARC-LRR proteins.

Quantitative trait loci Corresponds to genomic regions that is associated with the phenotypic variation of a quantitative trait.

Recessive allele An allele whose phenotypic effect is not expressed in a heterozygote.

Resistance gene Plant gene conferring resistance to a specific pathogen, that possess a corresponding avirulence gene.

RNA interference A broad antiviral defense system used by plants, animals, and fungi. It recognizes double-stranded RNA as a cue of viral presence and induces degradation or silencing of viral transcripts or genomes.

Transcriptional gene silencing A mechanism of gene silencing involving decreased RNA synthesis because of promotor methylation.

Virus immunity Genetic mechanism by which plants are unable to support replication of a virus, and consequently where the virus cannot be isolated by any mean from the infected plant.

Virus resistance Genetic mechanism by which plants are able to defend themselves against a viral invasion (by one or the other mechanism) that leads to reduced viral replication levels.

Virus tolerance Genetic mechanism by which plants are infected and viral replication/infection occurs at wild type levels but without any visual symptoms.

Virus-induced gene silencing It is a technology that exploits an RNA-mediated antiviral defense mechanism.

Introduction

Domestication of crops from their wild relatives has resulted in the loss of many resistance genes because these are often genetically linked to unwanted traits (such as low yield, poor flavor, small size). With the commercialization of agriculture and increasing production of crop plants in monoculture, genetic diversity has dwindled, which has made crops susceptible to a variety of pathogens. Therefore, breeding for resistance has consisted in reintroducing these resistance genes in the susceptible domesticated crop by crossing and selection. The wild relatives or ancestors of these crop plants present in their centers of origin or diversity are the best sources of resistance genes (R genes). Pathogen resistance in crop plants can also be generated by either natural or induced mutations. For example, Rice yellow mottle virus (RYMV) resistance in cultivated rice spontaneously appeared under RYMV pressure. Cassava varieties such as TME3 are also probably mutants which were selected under cassava mosaic disease pressure.

Geminiviruses are single-stranded, circular DNA viruses that cause economically important diseases in a wide range of crop plants across the globe. Geminiviruses are characterized by small geminate particles (18×30 nm) containing either one (A component, monopartite) or two (A and B components, bipartite) single-stranded circular DNA molecules of ~ 2.7 kb and sometimes associated with satellite DNA molecules of ~ 1.4 kb. Around 460 distinct species and a larger number of strains belong to the family *Geminiviridae*. In this article, we briefly discuss the resistance genes and the sources of resistance against the most important geminiviral diseases in cassava, tomato, bean, maize, and cotton.

An Overview of Natural Resistance to Viruses in Plants

Depending on the number of genes involved in providing the resistance phenotype, the host resistance can be classified into monogenic, digenic, or polygenic. Many of the monogenic and digenic types of resistance are qualitative in nature, with phenotypes showing complete absence of pathogen in the host plant. Whereas the polygenic resistance is manifested by several genes. A quantitative trait locus (QTL) is a region of DNA that is associated with a specific phenotypic trait, that varies in degree and can be attributed to polygenic effects, i.e., the product of two or more genes, and their interaction with the environment. Several such QTLs could be associated with one single trait. Such QTLs are mapped by genetic markers by using recombinant inbred lines (RILs) that are derived by crosses between parents with two contrasting resistance phenotypes. The inheritance pattern of the resistance trait can be dominant or recessive in nature and half of the virus resistance traits known hitherto are recessive in nature.

Plant R genes confer resistance to plant pathogens including plant viruses and each R gene confers resistance to a specific pathogen triggered by a specific avirulence (*avr*) gene or an effector protein. More than 80% of the R genes studied so far are monogenic in nature and one third of the R genes are tagged by molecular genetic markers. R-genes can be either dominant or recessive in nature. Studies done so far have shown that dominant R genes are of the NB-LRR (Nucleotide-Binding-Leucine-Rich Repeat) type and that recessive ones encode for translation initiation factors. Dominant gene resistance is usually associated with HR while recessive genes function at single cell level. R genes are known to show two unique patterns of clustering: in one case R genes with similar inheritance and resistance phenotypes are clustered at one locus, while in another case the R genes for virus resistance are clustered with unrelated R genes. Most of the recessive R genes identified to date are against potyviruses. Although there are no reports of R genes showing resistance to geminiviruses, there are reports of genetic mapping of the resistance loci through molecular markers. There are also reports demonstrating the interaction of geminivirus proteins with the trans-membrane receptor kinases and components of brassinosteroid signaling. It was recently shown that silencing of a *Permease 1-like protein* gene transmembrane transporter in tomato using the virus-induced gene silencing (VIGS) vector system, rendered it susceptible to Tomato yellow leaf curl virus. In response to the pathogen recognition by the R gene, changes in ion fluxes are observed, leading to activation of signaling pathways, alteration in transcriptional profiles, production of reactive oxygen species (ROS) and generation of nitric oxide (NO).

Gene silencing is another important mechanism which plants have evolved to defend against viruses. In plants, post-transcriptional gene silencing (PTGS) acts as a natural anti-viral defense system and is considered as part of the plant's innate immune system. RNA silencing involves suppression of gene expression by sequence-specific interaction at the transcriptional or post-transcriptional level in diverse eukaryotes. Double stranded RNA (dsRNA) is the trigger for gene silencing, which involves a chain of events to produce small interfering RNA (siRNA) through a diverse range of enzymes and its complexes, including the RISC-complex (RNA induced silencing complex) as well as DCL (Dicer-Like) and RDR (RNA dependent RNA polymerase) proteins. In virus-infected plants, RNA silencing is initiated by the double-stranded (ds) RNA that can be a viral replication intermediate or by 'aberrant' RNAs, or single-stranded RNA (ssRNA) that is converted to dsRNA by host-encoded RNA-dependent RNA polymerase (RdRP). The dsRNAs can also be formed because of bi-directional transcription of these viruses with transcripts occurring from opposite polarity overlapping at their 3'-ends, which partly explains how these geminiviruses induce PTGS in infected plants. Alternatively, the early and abundant transcripts of the AC1 gene of these geminiviruses can serve as the template for the host RdRP to produce dsRNAs. Yet another possibility is the fold-back structures of geminivirus transcripts which can serve as a template for DICERs to cleave at specific locations and produce siRNAs. In plants, some virus-host interactions naturally lead to host recovery that are similar to RNA-mediated virus resistance. This symptom recovery phenomenon is also reported for some of the geminiviruses (Fig. 1). This recovery phenomenon is associated with the production of virus-derived siRNAs, that later become abundant in the newly developed symptom-less recovered leaves. This increase in virus-derived siRNA accumulation is accompanied by a reduction in the levels of both viral DNA and mRNA accumulation.

Fig. 1 Symptom recovery in *Nicotiana benthamiana* plants infected by two distinct cassava mosaic geminiviruses (ACMV and EACMKV), as a result of gene silencing.

Since RNA silencing and R gene signaling are both components of the plants innate immunity, it will be interesting to know if there is any cross-talk between these two pathways through one of the systemic signaling systems such as the salicylic acid pathway. It has been shown that the RdRPs *NbRdRp1m*, *NtRdRp1* and *RDR1* are all inducible by both salicylic acid and certain viruses, although recent studies failed to find any overlap between the DCL endoribonucleases involved in silencing and the SA-induced resistance to positive-sense RNA viruses. More recently it has been shown that the virus resistance induced by NB-LRR proteins involved Argonaute4-dependent translational control. It has also been shown that the viral silencing suppressor HC-Pro enhances R-gene mediated resistance to viruses and this resistance is weak at higher temperatures. Geminiviruses are known to be associated with DNA satellites which modulate the viral symptoms and the betasatellites in particular are known to enhance the symptoms through their PTGS suppressor proteins (RC1).

In this article we discuss in greater detail and on a case by case basis the principal sources of resistance for the major geminiviral diseases of the world (Table 1).

Resistance to Cassava Mosaic Geminiviruses

It was recognized from the earliest period of research on cassava mosaic geminiviruses (CMGs) (Family *Geminiviridae*; Genus *Begomovirus*) that resistance would be the most effective method for controlling the cassava mosaic disease (CMD) caused by these viruses. The team responsible for the first biological characterization of CMGs in the former Tanganyika in the 1930s realised that wild relatives of cassava (*Manihot esculenta* Crantz) would provide an important potential source of resistance genes. Resistant progeny from *Manihot esculenta* × *Manihot glaziovii* (Müll-Arg.) crosses were backcrossed with cultivated cassava to produce the first CMD-resistant cassava varieties. Material from this initiative was subsequently used in the 1970s to extend the development of CMD resistance within the cassava breeding program of the International Institute of Tropical Agriculture (IITA). A recurrent selection approach was taken with the primary source of CMD resistance being the cassava clone 58308. It had been suggested since the 1950s that the resistance source derived from the *M. glaziovii* cross was polygenic, but this was also shown to be recessive in the early 1970s. During this period, evaluations of resistant varieties were undertaken in West, Central and East Africa, as well as in south India. Resistance was shown to be effective in all of these regions, providing a strong demonstration of the broad activity of the resistance source as well as its likely durability. We now know that there is significant virus diversity across these regions (ACMV, EACMV-like viruses, ICMV and SLCMV), which confirms the validity of the earlier conclusions about the broad-based activity of the *M. glaziovii*-derived resistance. This polygenic or quantitative recessive resistance source is now referred to as CMD1.

In the 1980s and 1990s in Africa there were extensive trial-based epidemiology studies of CMGs, several of which compared the responses of varieties with contrasting levels of resistance. Different components of resistance were identified, including: resistance to infection, resistance to virus multiplication, resistance to virus movement (leading to incomplete systemicity), and resistance of normal plant function to the effects of virus infection. These were assessed through measurements of virus titre, incidence of infected plants, severity of symptoms of infection, distribution of symptoms through the plant, and yield of healthy versus infected plants. Strong correlations were demonstrated between each of these variables. Resistant varieties were therefore infected less, had

less severe symptoms which were spatially limited in the plant, had lower virus titers and yielded more, demonstrating that each of these were expressions of the same resistance.

Following the increasing accessibility of PCR and sequencing analyses from the late 1990s onwards, it became possible to examine the molecular characteristics of CMD-resistant cassava varieties. A key development came in 2002 when a novel source of resistance to CMGs was identified from West African cassava landraces. Molecular genetic mapping was used to identify a single dominant gene referred to as CMD2, and this development made it possible for breeding programs to speed up their resistance breeding work through marker-assisted selection (MAS). Several markers were identified which could pick out clones carrying CMD2 with a high degree of reliability. Moreover, similar approaches also led to the identification of a third resistance source – CMD3 – in the genotype TMS97/2205. This clone also carried CMD2, and it was observed that the combination of CMD2 and CMD3 gave the plants very high levels of resistance to CMD. An additional spin-off from the development of MAS was that the technique could be applied in regions where CMGs did not even occur, but where there was an interest in having strategic stocks of CMD-resistant germplasm. This would allow these regions to respond rapidly to any future invasive spread of CMGs. This activity was pioneered by the International Center for Tropical Agriculture (CIAT) in Colombia, to prepare for the potential future introduction of CMGs to Latin America.

Fig. 2 (Top) CMD resistant cassava variety TME3 showing recovery from ACMV (2 weeks post inoculation) and EACMV (4 weeks post inoculation) infections in glasshouse experiments. Reproduced from Patil, B.L., Fauquet, C.M., 2015. Studies on differential behavior of cassava mosaic geminivirus DNA components, symptom recovery patterns, and their siRNA profiles. *Virus Genes*. 50 (3), 474–486. doi:10.1007/s11262-015-1184-y. (Bottom) CMD resistant and susceptible varieties of cassava cultivated in fields of Burundi.

In addition to extensive field evaluations for CMD resistance, targeted approaches such as microparticle bombardment using infectious clones have been used to screen for resistance to CMGs. In comparisons of ACMV and EACMV resistance, putative resistant accessions with CMD1, CMD2, or CMD3 were shown to have high levels of resistance to ACMV yet were severely affected by EACMV. The only exception to this was TMS97/2205 which was known to combine CMD1, CMD2, and CMD3. As a consequence of these and related findings, the primary objective of most cassava geminivirus resistance breeding programs is to combine these different resistance sources into varieties that also have favorable yield, organoleptic, and processing qualities.

There has been limited progress to date in identifying specific genes associated with CMD1, CMD2, and CMD3. However, transcriptome data have revealed differences between CMG-susceptible (T200) and CMG-resistant (TME3; Fig. 2) cassava varieties. Moreover, resistance gene analogs (RGAs) were also shown to be expressed differentially during the process of symptom recovery (from CMD infection), suggesting that they may provide a complementary resistance mechanism to RNA silencing. Methylation of viral DNA has been shown in several systems to be an important resistance strategy employed by plants against geminivirus infection and has been demonstrated specifically for ICMV. However, although resistance sources such as CMD2 have been pinpointed down to chromosome and linkage group level through genome-wide sequencing and mapping studies, further research is required before a more comprehensive understanding can be obtained of the genetics of the responses of cassava plants to virus infection.

While studies continue to expand knowledge about natural resistance to CMGs, there are widespread and highly successful programs being implemented to deploy CMD-resistant varieties (Fig. 2). These were disseminated throughout East and Central Africa to control the severe CMD pandemic of the 1990s/2000s with great success, and similar programs are now being used to address the more recent CMD pandemic in South-East Asia. Africa-derived CMD resistance has proven to be effective in controlling virus infection caused by the South Asian CMGs – ICMV and SLCMV – so they should also provide effective control for the currently spreading South-East Asian pandemic associated with SLCMV.

Geminivirus Resistance in Tomato

The Case of Resistance to Tomato Yellow Leaf Curl Virus

Tomato crops can be infected by a large number of geminiviruses (family *Geminiviridae*) mainly belonging to the genus *Begomovirus*. Tomato yellow leaf curl disease, one of the most devastating virus disease affecting tomato worldwide, is caused by a complex of begomoviruses originated in the Middle East but expanded initially to the Mediterranean Basin and then to the Far East, the Caribbean, North America, and Australia. Tomato yellow leaf curl virus (TYLCV) was the first monopartite begomovirus characterized and the most successful in spreading the disease worldwide.

Breeding for TYLCV Resistance

Breeding programs aimed at producing tomato varieties resistant to TYLCV started in the late 1960s and have expanded since (Fig. 3). These programs are based on the introgression of resistance found in some accessions of wild tomato species into the domesticated tomato (*Solanum esculentum*). Certain accessions of the wild tomato species *S. chesmanii*, *S. chilense*, *S. habrochaites*, *S. peruvianum*, and *S. pimpinellifolium* are resistant (with mild or no symptoms, but containing virus) to whitefly-mediated inoculation. The discovery of loci, and later on of genes, associated with TYLCV resistance, was facilitated by the development of saturated maps based on DNA polymorphism distinguishing resistance from susceptibility (RFLP, AFLP, SSR, SCAR, etc.).

To date, six loci, coined *Ty-1* to *Ty-6*, have been found to be associated with TYLCV resistance (Table 1). They have been mapped on different tomato chromosomes and five of them are independently inherited. The *Ty-1* and *Ty-3* loci originated from *S. chilense* accessions LA1969 and LA2779, respectively, and they were mapped to the long arm of tomato chromosome 6. Later, *Ty-3* was shown to be allelic to *Ty-1*. *Ty-2* was introgressed from *S. habrochaites* accession B6013 and was located on the long arm of chromosome 11. *Ty-4* was introgressed from *S. chilense* accession LA1932 and mapped to the long arm of chromosome 3. Compared to other *Ty* genes, *Ty-4* is less effective against TYLCV. *ty-5*, the only recessively inherited *Ty* gene known to date, was introgressed from *S. peruvianum* and mapped on chromosome 4. *ty-5* has been reported from different sources including line TY172 (derived from four different accessions of *S. peruvianum* which were crossed with *S. arcanum*) and tomato cultivar Tyking. *Ty-6* originated from *S. chilense* accessions LA1938 and LA2779 and was located on the long arm of chromosome 10. It has been shown that *Ty-6* is effective, in addition to TYLCV, against Tomato mottle virus, a New World begomovirus.

Pyramiding resistance from various wild tomato species in a single tomato line often broadens resistance. Today, most commercial tomato varieties resistant to TYLCV contain the *Ty-1* gene. Upon whitefly-mediated infection in the field and greenhouse, the plants remain symptomless and their yield compares with that of non-infected plants. However, reports in 2008 indicated that *Ty-1*-mediated resistance could be broken under high virus pressure. Worse, it was recorded in 2016 in Jordan and Israel that *Ty-1* resistant varieties suddenly became susceptible to TYLCV. Molecular cloning and sequencing indicated that the symptomatic plants were contaminated with the cotton leaf curl Gezira betasatellite, which in association with TYLCV, overcame the resistance based on *Ty-1*. These findings were later confirmed in the laboratory using cloned virus and betasatellite.

Characterization of Ty Genes

Three of the *Ty* loci have also been associated to genes which have been recently cloned and characterized.

Ty-1/Ty-3 were identified as coding for an RNA-dependent RNA polymerase (RdRp) belonging to the RdRp type which has an atypical DFDGD motif in the catalytic domain. It has been shown that *Ty-1* confers resistance to TYLCV and other begomoviruses by enhancing transcriptional gene silencing through an increase in cytosine methylation of viral genomes.

Ty-2 encodes a nucleotide-binding domain and leucine-rich repeat-containing (NB-LRR) gene, *TYNBS₁*. Introduction of genomic fragments containing the *TYNBS₁* gene into susceptible tomato plants resulted in transgenic lines resistant to TYLCV.

ty-5 is a loss-of-function mutant allele of the gene that encodes a messenger RNA surveillance factor Pelota (*Pelo*) located on chromosome 4. Pelota is involved in ribosome recycling phase of protein synthesis. The mutation in *ty-5* is caused by a T-to-G transversion in the coding region.

Ty-6 is located on chromosome 10, that compliments resistance conferred by both *Ty-3* and *ty-5* genes, thus providing resistance to both monopartite and bipartite begomoviruses.

Genetic Engineering for TYLCV Resistance

In some cases, as mentioned above for *Ty-2*, host-derived resistance has been engineered into susceptible tomato plants. Nonetheless, most of the tomato transgenic plants with incorporated begomovirus resistance were produced by expressing viral genes. TYLCV genes or gene segments, whether functional or not, have been used to confer a narrow as well as a broad-range virus-specific resistance (pathogen-derived resistance).

The expression of the TYLCV *CP* gene in an interspecific *S. lycopersicum* x *S. pennellii* hybrid was characterized by the late development of disease symptoms, often followed by their disappearance and recovery. The expression of the TYLCV *Rep* gene in tomato cultivars provided a virus-specific resistance. For example, tomato plants transformed with a truncated TYLCV *Rep* gene exhibited various degrees of resistance to TYLCV infection in the field in Florida. However, these TYLCV-resistant plants were susceptible to the bipartite begomovirus Tomato mottle virus conspicuous in Florida tomato fields. Similarly, tomato plants transformed with a 3' end-lacking *Rep* gene of Tomato yellow leaf curl Sardinia virus (TYLCSV, a monopartite begomovirus closely related to TYLCV) were resistant to TYLCSV from Italy but were susceptible to a cognate TYLCSV isolate from Spain.

Resistance was also achieved by mimicking the plant RNA interference (RNAi) antiviral mechanisms relying on pathogen transcriptional (TGS) and post-transcriptional (PTGS) gene silencing. Small interfering RNAs (siRNA) directed against TYLCV genes were designed, based on hairpin RNAi (hpRNAi), and used to produce transgenic tomato plants. It was found that hpRNAi-based resistance was highly sequence-specific. The first set of experiments using PTGS hpRNAi demonstrated that TYLCV and TYLCSV non-coding regions could trigger the accumulation of virus-specific siRNAs, followed by high levels of resistance against these two viruses. TYLCV *Rep* was also the target of hpRNAi. Homozygous transgenic tomatoes expressing hpRNAi TYLCV *Rep* were resistant to TYLCV in greenhouses and fields and carried large quantities of small RNAs. In addition, resistance was associated with changes in the general plant host transcriptome, mainly genes involved in biological regulation, metabolic and cellular processes such as catalytic and binding activities. The hpRNAi strategy has also been used against the *IR*, *CP*, *V2*, and *Rep* genes of TYLCV from Oman. The transgenic lines obtained exhibited various levels of resistance upon TYLCV agro-inoculation.

The CRISPR-Cas system, which protects prokaryotes from potentially deleterious foreign DNA, is the latest tool in the molecular breeder's panoply aimed at conferring TYLCV resistance. CRISPR-Cas was recently implemented to the making of virus-free crops, demonstrating that this technology can be applied to the molecular breeding of virus-immune tomatoes. Indeed, TYLCV resistance was conferred by editing the tomato genome. Targeting the TYLCV *CP* and *Rep* genes with Cas9 single RNA-guided DNA endonuclease resulted in stable resistance to the virus. The Cas9-treated tomato plants carried reduced TYLCV amounts and their progeny was resistant to TYLCV. Therefore, antiviral strategies based on genome editing have the potential to constitute an additional, maybe preferred, tool in the breeding of TYLCV-resistant tomato varieties.

Resistance to Beet Curly Top Virus

Beet curly top virus (BCTV, genus *Curtovirus*, family *Geminiviridae*), is a phloem-limited virus that causes curly top disease in several economically important crops such as common bean, pepper, sugar beet, and tomato. This disease is more prevalent and is known to cause heavy economic losses in the western USA, north-central Mexico and countries of the Mediterranean Basin and the Middle East (e.g., Iran and Turkey). Under favorable environmental conditions the disease outbreaks are driven by populations of the beet leafhopper vector (*Circulifer tenellus*).

Sources of curly top disease resistance have been identified in germplasm of common bean, flax, squash and sugar beet. However, the availability of commercially available resistant varieties that can be used in a management program for BCTV depends on the crop plant. Resistant varieties have played a major role in management of curly top in sugar beets and somewhat of a role in common bean, whereas there are no commercially available resistant varieties for pepper or tomato. In the early 1900s in the western USA, curly top disease emerged as a major constraint on sugar beet production, in some cases resulting in sugar refineries having to close. To search for resistance, mass selection from heavily infested fields led to the identification and release of the first curly top resistant sugar beet variety, US1, in 1933. This variety became widely grown in the western USA, despite some shortcomings. The identification and selection of resistant sugar beet varieties has been facilitated by the use of breeding plots, known as curly top nurseries, in which high populations of leafhoppers viruliferous for the most prevalent and virulent strains of BCTV are released. As a result of the high selection pressure in these nurseries, combined with the development of commercial hybrids and molecular breeding technologies, curly top resistance in sugar beet has advanced tremendously, despite this being a complex quantitatively inherited trait. Modern curly top resistant varieties have greater uniformity, higher yield and improved

resistance. However, plants of these resistant sugar beet varieties will develop curly top symptoms and may suffer yield losses when infected at an early stage of development (two to four leaf stage). Therefore, resistant varieties need to be part of an IPM program that addresses the susceptibility of young plants, e.g., seed treatment with systemic insecticides.

Common bean is another crop that can be heavily impacted by curly top in the western USA. Curly top resistance was identified in some common bean varieties (e.g., Red Mexican type). Genetic studies identified a single dominant gene (*Bct-1*) associated with curly top resistance in common bean. Breeding efforts led to the release of the commercial curly top-resistant varieties Great Northern UI 15 and Red Mexican UI 34. Subsequently, snap bean varieties with curly top resistance were developed and released. These varieties have provided acceptable yields under high curly top pressure. Now there is a need to develop curly top-resistant varieties for other classes of common bean.

In terms of tomato and pepper, curly top resistance was not found in commercial cultivars. However, high levels of resistance were found in accessions of some wild species of tomato, including *Solanum chilense*, *S. habrochaites*, *S. lycopersicoides* and *S. peruvianum*. Unfortunately, introgression of this resistance into commercial tomato varieties has been difficult. However, as described in the case of resistance to TYLCV, a series of 6 loci (genes) conferring some degree of resistance to the virus, have been introgressed into tomato breeding lines. These lines have been used to generate commercial varieties with effective resistance against monopartite begomoviruses such as TYLCV. The mechanisms of Ty gene products determined to date, such as the Ty-1/Ty-3 enhancing transcriptional gene silencing (TGS) and cysteine methylation of the viral genome, appear to be common to all geminiviruses rather than genus-specific. Therefore, BCTV agro-inoculation screening was used to assess the response of 15 breeding lines, having different combinations of Ty genes (e.g., Ty-1, Ty-2, Ty-3, ty-5, and Ty-6), kindly provided by the World Vegetable Center. The response was assessed based upon a 0–4 rating scale, with 0=no symptoms to 4=severe stunting and leaf curling and vein purpling. In screens with the BCTV-Svr-[US: SVR:Cfh], the susceptible control received a rating of 4.0, whereas 11 of the breeding lines had ratings <2.5, with three lines with rating of 1.5–1.7 (lines with Ty3 only, Ty3 and Ty2 and Ty5 and Ty6). In an equivalent screen with BCTV strain BCTV-LH-71-[US: Cal:10], which was associated with the 2013 curly top outbreak in processing tomatoes in California, only 6 of the Ty breeding lines had ratings <2.5, with two lines having ratings of 0.9 and 1.2 (both having the Ty2 and Ty3 combination). Together, these results indicate that pyramiding Ty genes in tomato can provide resistance to BCTV, consistent with these gene products targeting a general geminivirus property, such as replication or transcription. Importantly, the effectiveness of the resistance was not the same for two strains of BCTV. A similar result was reported in the reverse scenario in common bean, where the *Bct-1* gene that confers qualitative (strong) resistance to BCTV, provided a high level of quantitative resistance to the bipartite begomovirus, Bean dwarf mosaic virus (BDMV). These results suggest the possibility of generating broad spectrum geminivirus resistance.

To assess the potential for using Ty genes to generate a curly top resistant tomato variety, a breeding line was generated by screening progeny of crosses aimed at pyramiding the Ty-1, Ty-2, and Ty-3 genes by agro-inoculation. Plants with a resistance phenotype were then selected and further selection performed by selfing plants and screening progeny by agro-inoculation. The breeding line that was generated, named Line 20#12, carries the Ty-1, Ty-2, and Ty-3 genes and has moderate to strong resistance to curly top (Fig. 4). Moreover, the resistance in this line involves initial development of mild up-curling and vein purpling in the first true leaves, followed by a recovery phenotype in which all subsequently emerging leaves show no symptoms (although virus can be detected in these leaves). This resistance phenotype is consistent with TGS targeting the BCTV genome for methylation, reducing transcription and replication. Thus, these results suggest that pyramiding Ty genes in a commercial tomato background could be a strategy to generate commercial curly top-resistant varieties.

Geminivirus Resistance in Beans

Geminiviruses cause severe diseases in common bean (*Phaseolus vulgaris*), and also in other species of *Phaseolus* such as lima bean (*P. lunatus*). In the Americas, the viral species involved are Bean golden mosaic virus (BGMV), Bean golden yellow mosaic virus (BGYMV) and Macropitium yellow spot virus (MaYSV), all of which cause similar symptoms of severe yellow ("golden") mosaic. BGMV and MaYSV occur in South America (MaYSV has so far been only reported in Brazil), while BGYMV is present throughout Central America and the Caribbean.

Many institutions in the Americas had breeding programs for resistance to golden mosaic disease in *Phaseolus*. The most successful program was conducted at the International Center for Tropical Agriculture (CIAT) in Cali, Colombia, starting in the mid-1970s. This program targeted BGYMV, although most of the relevant literature refers to BGMV, since the distinction between the two viruses was not completely clear at the time. Indeed, the fact that resistance to BGYMV was not successful against BGMV provided additional evidence for the distinction between the two viruses. A first source of resistance to BGYMV was identified in a black bean landrace named Porriño Sintético, originated from El Salvador (Central America). The analysis of segregating populations derived from crosses with this source indicated that resistance was quantitative. Resistance was partial and often broke down under high inoculum pressure. The red-seeded line DOR 364 provided additional quantitative resistance genes, and a number of cultivars containing these two sources, with resistance that was markedly superior to that conferred by either source alone, were released during the 1980s. During that decade, virtually all resistant cultivars that were deployed in Central America and the Caribbean derived from these two sources. These cultivars were largely responsible for the recovery of bean yields in that region. The main limitation with these sources of resistance was that all resistant cultivars produced black seeds, and many of the commercial common bean cultivars grown in disease-prone regions had different seed colors that were changed when crossed with

Fig. 4 Advancement and characterization of tomato breeding lines for beet curly top virus resistance, by agro-inoculation of BCTV in glasshouse conditions at the University of California, Davis, CA, USA.

the black-seeded parental sources of resistance. Moreover, resistance was not complete and could still be overcome in years when conditions were highly favorable to the disease.

An improved source of resistance was identified in the early 1990s in Garrapato, a landrace from the Durango group from Mexico. A breeding line derived from Garrapato, named A429, provided the best level of resistance. Inheritance studies indicated that the resistance in A429 was controlled by a single recessive gene, named *bgm-1*. The presence of the *bgm-1* gene strongly reduces the mosaic and yellowing symptoms caused by BGYMV. The *bgm-1* containing DOR lines developed by the breeding program at CIAT remain the best source of durable and stable BGYMV resistance (Fig. 5).

A co-dominant sequence-characterized amplified region (SCAR) marker, SR2, which is tightly linked to *bgm-1*, was developed by genetic mapping. The position of the *bgm-1* gene was estimated to be close to that of *bc-1*, which confers resistance to the potyvirus Bean common mosaic virus (BCMV), on chromosome 5. Interestingly, the mapping study indicated that *bgm-1* may be sub-telomeric. Sub-telomeric regions tend to be highly recombinogenic, a characteristic that is advantageous in the context of host-pathogen co-evolution.

The success at obtaining resistant varieties to BGYMV was not, unfortunately, replicated in South America for BGMV (a different virus with a low degree of sequence identity with BGYMV). Breeding for resistance to BGMV initiated in the 1970s at the Campinas Agronomical Institute (IAC in the Portuguese acronym) in Campinas, Brazil, and also at center for bean research at Embrapa, in Goiânia. Although a number of varieties with delayed incidence of the disease were obtained, inheritance was complex, yields were

Fig. 5 The "Mosaico Dorado Amarillo de Frijol" (Bean golden yellow mosaic virus) nursery established at San Andrés Experimental Station of the Centro Nacional de Tecnología Agropecuaria y Forestal "Enríques Álvarez Córdova" in El Salvador (Central America), as part of the breeding program conducted by CIAT. The nursery contains a large number of landraces and breeding lines of black and red beans with different levels of resistance to Bean golden yellow mosaic virus (BGMV). Courtesy of M.A. Grajales.

unremarkable, and their agronomical traits were not generally favored by growers. The most promising varieties were released during the 1990s by the breeding program at the Paraná Agronomical Institute (IAPAR) in Londrina. However, the quantitative, partial resistance provided by these lines would break down under the high BGMV incidence levels that often occurred in southern Brazil. The lack of success at obtaining cultivars with good natural resistance to BGMV led to the development of a genetically modified common bean, based on RNAi technology, which provided excellent resistance.

Resistance to Mungbean Yellow Mosaic Viruses

In black gram (*Vigna mungo*) Mungbean yellow mosaic India virus (MYMIV) resistance is governed by a single recessive gene having NB-ARC domain with normal functional group. A resistant gene (CYR1) for MYMIV has been characterized, similarly its truncated allele (*cyr1*) was also found in susceptible black gram. Moreover, a SNP in LRR-like protein kinase gene responsible for a G/C transversion was identified in soybean. The yellow mosaic disease (YMD) was found to be monogenic. The comparative transcriptome analysis showed an upregulation in NAC transcription factor, Argonaute, NB-LRR, Ankyrin and WRKY33 genes. Full length cDNA of black gram MAPK (Mitogen-activated protein kinases) designated as *VmMAPK1* was found increased during MYMIV infection, which helps in autophosphorylation and restricting the multiplication of MYMIV by mediating salicylic acid signaling pathway. MAPK16 and MAPK3 genes are down regulated during MYMIV infection. Moreover, the G2/mitotic specific cyclin-1-like and Cyclin-B1 (CYCB1) were found up-regulated. MYMIV interacts with proliferative cell nuclear antigen, recombination-dependent replication (RDR51, RDR54), minichromosome maintenance protein subunit 2 (MCM2) and replication protein A, respectively. Micro RNAs (miRNAs) also confer resistance against MYMIV such as *gma-miR5785* found in soybean, that helps in cleavage of BC1 gene of MYMIV. In Mungbean RAPD markers OPP 07₈₉₅ and OPP 07₉₀₀ are associated with Mungbean yellow mosaic virus (MYMV) resistance, while OPP 07₇₃₀ was found in French bean.

A resistance gene analog (RGA) marker has been associated with MYMV resistance in mungbean and black gram. Moreover, the MYMIV-resistant markers YR4 and CYR1 were found in urdbean and mungbean. In black gram the SSR marker (CEDG180) was found closely linked with YMD resistance. The QTLs (qTMIV1 to qYMIV5), qMYMIV2 and qMYMIV were identified for MYMIV resistance in *Vigna radiata*. The SSR marker CEDG044 was found highly linked with MYMIV resistance. The MYMIV resistance gene was mapped on chr 6 (LG C2), which is present 3.5-cM on genomic region between two SSR markers GMAC7L and Satt322. Similarly, in black gram the ISSR8111357 marker was developed and confirmed for MYMV resistance. **Fig. 6** illustrates the screening of soybean germplasm for resistance to Mungbean yellow mosaic virus.

Resistance to Cotton Leaf Curl Virus in Cotton

Livelihoods of many rely on cotton in many countries across the world. Cotton leaf curl viruses (CLCuVs), members of the genus *Begomovirus*, in the family *Geminiviridae*, and their natural vector whitefly (*Bemisia tabaci*) pose serious threat to cotton production. In the Indian subcontinent, whitefly-mediated cotton leaf curl disease (CLCuD) stands a devastating factor that limits overall production of cotton. Multiple strategies based on pathogen-derived resistance have been tried but huge diversity of geminiviruses has resulted in limited success under field conditions. *Gossypium hirsutum*, tetraploid cotton cultivars produce high quality lint and fiber but are susceptible to CLCuD. On the contrary, one of the diploid progenitors of cotton, *G. arboreum* (A genome) is resistant to CLCuD, making it a valued source for novel genes to improve CLCuD resistance. Whole transcriptome analysis of *G. arboreum* under graft-mediated CLCuD infection revealed the genetic basis and underlying mechanism of resistance. The genes related to oxidative stress, transcription factors, R-gene family, phytohormone signaling, membrane transporters and channel proteins were found differentially expressed and may be involved in resistance to CLCuD. Correlation

of these identified genes with available QTLs (associated with CLCuD resistance) can help in picking the desirable genes further to impart CLCuD resistance in cotton.

Several efforts have been made for the identification of resistance sources among large collections of available cotton germplasm (Fig. 7). Around 5000 cotton USDA germplasm accessions from their different breeding programs were screened against a high pressure of CLCuD. This massive screening revealed a disease resistant accession Mac7.

The understanding of mechanisms underlying the interaction of virus, whitefly and host cotton plant can help in devising robust strategies for controlling the virus and vector (Fig. 8). Therefore, transcriptome analysis of Mac7 under whitefly-mediated CLCuV infestation has shed light on the molecular insights of CLCuD and whitefly resistance in cotton. This study has pinpointed the involvement of heat shock proteins and geminivirus-interacting genes in Mac7 resistance to CLCuD. Virus-induced gene silencing (VIGS) based silencing of HSC80, E3 ligase and serine threonine kinase (STK) genes exhibited increased susceptibility to whitefly and CLCuD in Mac7 cotton. These identified genes in resistant cotton accession could be used as useful sources of resistance to CLCuD and can help in improving the whitefly and virus resistance in cotton germplasm.

Understanding and exploitation of host plant resistance against whitefly can also help in control of geminiviruses. In this context, a study in cotton infested with whitefly showed differential gene expression of WRKY40, GhMPK3 and copper transport protein. Furthermore, VIGS of GhMPK3, validated the suppression of Jasmonic acid (JA) and Ethylene (ET) signaling related genes leading to the whitefly susceptibility. Small RNA-seq and genome-wide miRNA analysis of whitefly resistant and susceptible cultivars of *G. hirsutum* has been done recently, that revealed the involvement of miRNAs related to leucine-rich repeat (LRR) protein, MYB transcription factors and auxin response factor (ARF). VIGS of ARF8 from whitefly resistant cotton targeting miRNA390 enhanced the auxin and JA accumulation that increased the whitefly tolerance. Susceptible cotton variety of *G. hirsutum* when infected with CLCuD viruliferous whiteflies indicated the differential gene expression of genes including transcription factors (NAC, bHLH, MYB), heat shock proteins, methyl-transferases and metabolism related genes like cytochrome p450. Thus the genes identified and highlighted in these studies can be used in developing and enhancing cotton resistance to whitefly.

Now in the era of new plant breeding technologies, CLCuD/whitefly resistant cotton cultivars harboring ample genetic diversity can be achieved using CRISPR/Cas9 system. CRISPR/Cas9 based gene targeting is now becoming a method of choice with high reliability and efficiency for cotton genome editing. It would help in targeting CLCuD related susceptibility genes in cotton to

Fig. 8 *Geminivirus (CLCuV)/whitefly – cotton interactions and mechanisms of host plant resistance.* Cotton leaf curl geminivirus disease complex entry into cotton through whitefly mediates different layers of mechanisms in cotton to deal with pest and virus including interaction of geminivirus proteins with plant genes, activation of differential gene expression, miRNA machinery, metabolic changes and phytohormone signaling pathways.

counter the whitefly and fast evolving viral genomes. Moreover, development of improved resistant crop varieties by bridging the conventional and new genetic approaches along with pest/disease awareness to the farmers, capacity building of researchers would be helpful in controlling the geminiviruses and related diseases effectively.

Resistance to Maize Streak Virus

Maize streak virus (MSV, genus *Mastrevirus*, family *Geminiviridae*) causes maize streak disease (MSD), one of the most important viral diseases of maize in sub-Saharan Africa. MSV largely remains uncontrolled in most of the African continent and during epidemic years it can lead to widespread yield losses and famine. Fig. 9 depicts field performance of a MSV resistant maize variety “TZL composite 4L” along with a MSV susceptible maize variety “Gusau Pool 16” in Nigeria. Resistance to MSV is associated with up to five different QTLs located on chromosome 1, 3, 7, and 9, that are either dominant or additive in nature (Table 1). None of these QTLs in isolation can prevent MSV infections, however combinations of them can resist the MSV infections. Although maize

genotypes that tolerate MSV infection without compromising much with yield losses have been developed, there has been only limited success in the field. The MSV resistance seems to be specific to certain geographic locations, selection made of MSV resistance at one location may fail to tolerate MSV infections in another location. Thus the breeding efforts and screening for MSV resistance have to be specific to different geographical areas or the agro-climatic zones of Africa. One of the major concern is that the improved MSV tolerant maize genotypes don't have the desirable agronomic traits, such as good yields. Thus developing maize genotypes that possess both MSV tolerance and high yields remains a big challenge to the maize breeders. Further involvement of multiple MSV tolerant QTLs makes it difficult to introgress each of them in one single maize genotype and development of such a variety may take several years of breeding. Despite the humungous efforts made in development of MSV resistant maize varieties, most farmers prefer to use high-yielding maize varieties.

Conclusion

The current knowledge on the genes that confer resistance to geminiviruses is scarce when compared to the information available for plant infecting RNA viruses. Although the geminivirus resistant locus/loci are mapped in several cultivated plant species, the actual genes associated with the resistance are yet to be cloned and characterized. The few resistant genes that have been identified, the underlying resistant mechanism is yet to be understood. In this article we have summarized the sources and genes for geminivirus resistance in the most important crop plants that are heavily infested by geminiviruses. The geminivirus resistant genes identified so far are diverse in their characteristics, they are monogenic and polygenic, dominant and recessive, and specific as well as broad spectrum in nature. Introgression of these resistant genes in cultivated crop varieties has not been very successful since some of these genes are associated with poor agronomic traits. Loci or genes conferring resistance to the whitefly vectors are not yet identified and identification of such genes may boost the breeding for begomovirus resistance. Revolution in genome editing technologies and employment of CRISPR-Cas based technologies for precise editing of host genes are promising for manipulating the recessive resistant genes that makes them immune to geminivirus infections. Transgenics by employing CRISPR-Cas technology that destroys the geminiviral DNA genome have been developed, however their durability remains uncertain with reference to the fast mutating geminiviruses which may evade the targeting by sgRNAs that are key for Cas9 based cleavage. However, these are considered as transgenics and their social acceptance is questionable. Thus emphasis on identification and characterization of novel geminiviral resistant genes offers more promise for development of improved geminivirus resistant crop varieties.

Glossary

Chytrid fungi Obligate parasitic root-infecting fungi of the *Chytridiomycetes* that rarely appear to affect the host plants but act as vectors for plant viruses, for example *Olpidium virulentus*.

L protein Main component of the viral polymerase complex, responsible for replication and transcription with RNA-dependent RNA polymerase, mRNA 5′ capping, 3′ polyadenylation and protein kinase activities.

Leader and trailer Regulatory regions at the 3′ and 5′ termini of rhabdovirus genomes that show a high degree of sequence complementarity and are predicted to form a panhandle structure during replication.

Negative-sense RNA viruses Have negative-sense single-stranded RNA as their genetic material. Genomic RNA of negative polarity is complementary to the mRNA that is transcribed from it for translation of encoded proteins. Purified negative-sense RNA by itself is not infectious but requires viral core proteins to commence replication and transcription.

Nucleocapsid core The transcriptionally-competent ribonucleoprotein that represents the minimal infectious unit of rhabdoviruses.

Viroplasm The site of viral RNA replication, transcription and nucleocapsid formation.

Introduction

‘Classic’ plant rhabdoviruses have distinctive enveloped bacilliform or bullet-shaped particles and are distinguished based on whether they replicate and undergo morphogenesis in the cytoplasm or in the nucleus. Consequently, they have been classified in two genera, *Cytorhabdovirus* or *Nucleorhabdovirus*. More than 70 putative plant rhabdoviruses have been described over the years based on their morphology although, in many cases, molecular characterizations necessary for unambiguous classification are incomplete or lacking. More recently, an increasing number of novel plant rhabdovirus genomes have been assembled from high throughput sequencing data of diverse plant and insect species. All sequenced plant rhabdoviruses have the same general genome organization as other members of the *Rhabdoviridae*, and each encodes at least six open reading frames (ORFs), one of which facilitates cell-to-cell movement of the virus. Thus, plant rhabdoviruses have a number of similarities to members of other rhabdovirus genera, but they differ in several respects from rhabdoviruses infecting vertebrates. Two new genera of bisegmented plant viruses were recently classified as rhabdoviruses, the dichorhavirus that infect horticultural and ornamental plant species and are transmitted by *Brevipalpus* mites, and the varicosaviruses that are transmitted by chytrid fungi.

Rhabdoviruses infect plant species from a large number of different families, including numerous weed hosts and several major horticultural and cereal crops. Symptoms of infection vary substantially and range from stunting, vein clearing, mosaic, and mottling of leaf tissue, to tissue necrosis. The most serious pathogens include Maize mosaic virus (MMV), Lettuce necrotic yellows virus (LNYV), Rice yellow stunt virus (RYSV), Rice stripe mosaic virus (RSMV), Eggplant mottled dwarf virus (EMDV), Strawberry crinkle virus (SCV), Potato yellow dwarf virus (PYDV), Barley yellow striate mosaic virus (BYSMV), Northern cereal mosaic virus (NCMV), Orchid fleck virus (OFV), and Coffee ringspot virus (CoRSV). A number of other rhabdoviruses also have disease potential that can be affected by agronomic practices, incorporation of genes for disease resistance, and control of insect vectors.

The transmission of most plant rhabdoviruses is dependent on specific phytophagous insects that support replication of the virus. Therefore, viral prevalence and distribution is influenced to a large extent by the ecology and host preferences of their vectors. Although some rhabdoviruses can be transmitted mechanically by abrasion of leaves, this mode of transmission does not contribute significantly to their natural spread due to the labile nature of the virion. Moreover, seed or pollen transmission of plant rhabdoviruses has not been described; thus, aside from vegetative propagation, direct plant-to-plant transmission is unlikely to be a major factor in the ecology or epidemiology of these pathogens.

This article focuses on recent findings concerning the taxonomy, structure, replication, and vector relationships of the expanded group of plant rhabdoviruses. More extensive aspects of plant rhabdovirus biology, specifically ecology, disease development and control, can be found in earlier reviews.

Taxonomy and Classification

Plant rhabdoviruses are taxonomically classified in the order *Mononegavirales*, family *Rhabdoviridae*. The International Committee on Taxonomy of Viruses (ICTV) in its 9th Report (2011) listed two genera containing plant rhabdovirus species, *Cytorhabdovirus* and *Nucleorhabdovirus*, the members of which have unsegmented genomes and are discriminated by their replication and morphogenesis in the cytoplasm and nucleus, respectively of infected cells. For the 10th Report (2018), the genera *Dichorhavirus* and *Varicosavirus* were added to the family, based on phylogenetic relatedness of its members to the rhabdoviruses. The genus *Dichorhavirus* was newly created, whereas *Varicosavirus* had not previously been assigned to a family. Dichorhaviruses are most closely related to nucleorhabdoviruses, but have a bisegmented genome and virions do not appear to be enveloped. Varicosaviruses will not be discussed further in this chapter.

In 2019, in the family *Rhabdoviridae*, out of the 19 recognized genera 4 contain plant viruses. The ICTV has listed eleven accepted plant virus species in the genus *Cytorhabdovirus*, ten in the genus *Nucleorhabdovirus*, five in the genus *Dichorhavirus* and one in the genus *Varicosavirus*, a total of 27 plant virus species out of 289. Phylogenetic analyses of these rhabdoviruses have confirmed their taxonomic classification, although it has become evident that following inclusion of the dichorhaviruses, the genus *Nucleorhabdovirus* no longer has a monophyletic origin (Fig. 1) and will need to be split. The genomes of more than 20 novel plant rhabdoviruses have been recently identified by high throughput sequencing and await official classification. However, many plant rhabdoviruses that were identified before next generation sequencing technologies were available have not been investigated in much detail beyond cursory infectivity studies, crude physicochemical analyses of virus particles, and electron microscopic observations of morphogenesis. Consequently, more than 70 putative rhabdoviruses await assignment to a species and genus once genome sequences can be obtained. Viruses characterized in greater detail, with coding sequences deposited in GenBank, that have approved or pending taxonomic assignments are listed in Table 1.

Particle Morphology and Composition

In comparison to rhabdoviruses restricted to vertebrate hosts, plant-adapted rhabdoviruses are typically bacilliform in shape (Fig. 2). The modal lengths of particles, measured by electron microscopy of thin sections, range from 45 to 100 nm wide by 130–350 nm in length. Suggestive of packaging genomic RNAs in separate particles, particles of dichorhaviruses and varicosaviruses tend to be approximately half the length of rhabdovirus particles. While dichorhavirus particles lack a lipid envelope, those of the majority of rhabdoviruses consist of an outer layer of host-derived membranes, the lipid composition of which is commensurate with that of the membrane environment where morphogenesis occurs, be it on the nuclear envelope (NE) or endoplasmic reticulum (ER) (Fig. 2(b)). Protruding from the envelope is the spike glycoprotein (G) that is distributed more or less uniformly around the virion (Fig. 2(a)). Serving to both stabilize the particle and connect the G-containing envelope to the condensed nucleocapsid (NC) is the matrix protein (M). However, the biological functions of M may extend far beyond that of its structural role. The NC contained within the virion is a ribonucleoprotein complex composed of single-stranded negative-sense RNA, encapsidated over its entire length by the nucleocapsid protein (N) (Fig. 2(a)). Associated with this complex are small amounts of the viral phosphoprotein (P) and large (L) RNA-dependent RNA polymerase (RdRp). This “core” NC is transcriptionally competent for synthesizing viral mRNAs once it gains entry to cells compatible for replication. Collectively, virions of plant rhabdoviruses have a composition that is approximately 70% protein, 2% RNA, 20%–25% lipid, with a minimal fraction of carbohydrate associated with the G protein. Genomic RNAs of plant rhabdoviruses tend to range from 10 to 15 kb, while those of dichorhaviruses, and varicosaviruses are 5–6 kb for each segment.

Genome Structure and Organization

The general genomic structure of plant rhabdoviruses is conserved in a manner similar to that of the prototypical rhabdoviruses like Vesicular stomatitis virus (VSV) or Rabies virus. As such, the protein-encoding open reading frames (ORFs) are flanked by short untranslated leader (ldr), and untranslated trailer (trl) regions, at the 3' and 5' ends of the genomic RNA. These regions show a high degree of sequence complementarity (Fig. 3(a)) and are thought to potentially form a panhandle structure of the genome during

Fig. 1 Maximum likelihood (ML) phylogeny of plant rhabdoviruses. L protein amino acid sequences of selected plant rhabdoviruses (cytorhabdoviruses, nucleorhabdoviruses, dichorhaviruses, and varicosaviruses) and two well-known animal rhabdoviruses (as outgroup) were multiple aligned using MAFFT version 7. Subsequently, ambiguously aligned regions were trimmed with Gblocks. A ML tree was constructed based on the sequence alignment using PhyML 3.0 with the best fit model LG with + I + G + F. The types of plant host and arthropod vectors are differentiated by circles filled with different colors (monocot and dicot) or shaded cartoons, respectively. An asterisk following the virus name indicates that the vector has not yet been determined. Numbers at the nodes indicate bootstrap values > 50%. replication. Located between each ORF are so-called intergenic or “gene-junction” sequences (IGSs) that provide cis-regulatory elements for transcription and replication. IGSs have a modular structure composed of three elements, (1) Module 1; a poly(U) tract at the 3′ end of each gene located after the un-translated region (UTR) of the preceding ORF, (2) Module 2; a di- to poly-nucleotide spacer typically starting with a guanyl residue that is not templated in mRNAs, (3) Module 3; a transcriptional “start” sequence that is typically a tri- to penta-nucleotide sequence found in each of the viral mRNA transcripts (Fig. 3(b)).

Table 1 Characteristics of plant rhabdoviruses, members and/or tentative members of 4 genera of the family *Rhabdoviridae*. Only accessions of complete or coding-complete genome sequences are provided. Type species are in bold

Genus/Species	Acronym	Genbank accession		Host plant	Arthropod vector
Cytorhabdovirus

Fig. 2 Virion structure and morphology of enveloped plant rhabdoviruses. (a) Stylized virion structure of an enveloped, unsegmented plant rhabdovirus. The left side of the figure shows the approximate orientation and shape of the glycoprotein (G) and lipid bilayer envelope (orange). The matrix protein (M; blue hexagons) connects the envelope to the condensed nucleocapsid core, which is composed of the genomic-length single-stranded RNA, encapsidated by the nucleocapsid protein (N; red circles). Associated with this RNA-N complex are the phosphoprotein (P; yellow circles), and the large (L) RNA-dependent RNA polymerase (blue circle). (b) Transmission electron micrograph of a thin-section of sonchus yellow net virus-infected leaf tissue of *Nicotiana benthamiana*. Note accumulation of bacilliform shaped virus particles (V) in the perinuclear space between the outer (ONM) and inner (INM) membranes of the nuclear envelope (NE). Nucleocapsids are condensed in the viroplasm (VP) that is highly enriched with P protein prior to migrating to the NE where morphogenesis takes place. Fig. 4 Schematic diagrams of the genome organization of representative plant rhabdoviruses classified in the genera *Nucleorhabdovirus*, *Cytorhabdovirus*, *Dichorhavirus*, and *Varicosavirus*. See [Table 1](#) for full virus names. Each open reading frame (ORF) is indicated by an arrow labelled with the name of the encoded protein (N = nucleocapsid protein; P = phosphoprotein; M = matrix protein; G = glycoprotein; L = Large polymerase). Accessory genes are shaded in grey and numbered. In some cases, ORF 3 has been shown to encode a cell-to-cell movement protein.

In all genomes characterized to date the N ORF follows immediately after the leader, and the large (L) RdRp ORF precedes the trailer region. Situated between these ORFs are three additional protein coding regions conserved in all rhabdoviruses, namely the P protein, M protein, and G protein. Interspersed between these conserved ORFs are additional coding regions peculiar to plant-adapted viruses generally, or unique to a particular virus. These regions, typically designated as 'P3' or 'P6' are located in genomes in the general order 3'-Ldr-N-P-P3-M-G-P6-L-trl-5' ([Fig. 4](#)). The number of ORFs between the P and M genes may be variable. Overall, the plant rhabdovirus genomes analyzed so far contain between 6 and 10 ORFs ([Fig. 4](#)). Proteins encoded in position P3 ([Fig. 4](#)) have long been predicted, and recently experimentally demonstrated, to be required for the cell-to-cell movement functions essential for all plant viruses.

The general gene order and genome structure of plant rhabdoviruses are also conserved in the dichorhviruses and varicosaviruses. Key distinctions are that the N to G ORFs are encoded on RNA1 in dichorhviruses, and on RNA2 in varicosaviruses, while the cognate L polymerases are encoded on RNA2 and RNA1, respectively ([Fig. 4](#)).

Properties of Viral Proteins

Comprehensive biochemical, molecular, subcellular localization, and protein-protein interaction analyses of plant rhabdovirus-encoded proteins have been carried out mostly with the *Sonchus yellow net virus* (SYNV), PYDV, LNYV, and OFV models. Putative functions have been assigned to proteins encoded by less-well studied plant rhabdoviruses on the basis of their genomic locations and sequence relatedness to plant and animal model rhabdoviruses. Overall, amongst the five structural proteins of plant

Fig. 5 Confocal micrographs of leaf epidermal cells of transgenic *N. benthamiana* expressing RFP targeted to endomembranes. (a) in the absence of virus, RFP accumulates in the envelope of the nucleus (N). (b) Infection by the nucleorhabdovirus SYN V results in intranuclear accumulation of the inner nuclear membrane. The resulting expansion of perinuclear volume fills with the RFP-ER marker. In the image planes shown here, the reticulate pattern of the ER is not visible in the cytoplasm (C). (c) Within SYN V-infected nuclei, nucleocapsid formation takes place in viroplasm “rings” that are highly enriched in P protein (expressed here as a fusion to green fluorescent protein, in transgenic plants expressing the nucleolar marker protein RFP-Fibrillarin 1). Scale bar = 2 μ m.

rhabdoviruses, the L protein has conserved polymerase motifs common to all mononegaviruses, whereas the N, P, M, and G proteins are less conserved and have only limited sequence relatedness to analogous proteins of animal rhabdoviruses.

The Nucleocapsid Protein (N)

The N protein functions to encapsidate the entire viral RNA genome and tightly packages it to form NC that are RNase-resistant (Fig. 2(a)). VSV N protein has a tendency to form large aggregates and binds cellular RNAs non-specifically. Interactions of P protein with free N protein form a soluble complex, designated N(0)-P, which selectively encapsidates viral RNA. The availability of N(0)-P complexes regulates a critical switch from transcription to replication in the viral infection cycle, since genome replication entails encapsidation of nascent RNAs and only the encapsidated form of the genome can serve as template for viral polymerase. Biochemical experiments have shown that the solubility of SYN V N protein is increased upon co-expression and interactions with the P protein, so the SYN V P protein appears to have a similar chaperone function to keep the N protein in a biologically active form.

The N protein is also a major component of the viroplasm, the site of viral RNA replication, transcription and NC formation (Fig. 5). Confocal microscopic studies have revealed the subcellular localization of N proteins of selected cyto- and nucleorhabdoviruses consistent with their role in viroplasm formation. For instance, the N protein of the cytorhabdovirus LYNV localizes to the cytoplasm, whereas the homologs from the nucleorhabdoviruses SYN V, PYDV, MMV, Maize fine streak virus (MFSV), and RYSV are targeted to subnuclear foci. When the N proteins were co-expressed with their respective cognate P proteins, the N-P complexes co-localized to distinct cytoplasmic (in the case of LYNV) or subnuclear (SYN V, PYDV, OFV, etc.) inclusions characteristic of viroplasms, which are often different from the localization of either protein alone. In SYN V, formation of these subnuclear foci requires self-interactions of the N protein that are mediated by a helix-loop-helix motif near the amino (N)-terminus, as well as interactions of the P protein with the N-terminus of the N protein. However, heterologous combinations of SYN V and MFSV N and P proteins fail to form subnuclear foci. These co-localization studies suggest that cognate N-N and N-P protein interactions are essential for viroplasm formation.

The N proteins of nucleorhabdoviruses and dichorhavirus contain a nuclear localization signal (NLS) for nuclear import. Experiments conducted in plant and yeast cells have shown that SYN V and PYDV N proteins contain a bipartite NLS near the carboxy (C)-terminus that is required for nuclear localization, and biochemical studies have shown that the N proteins interact *in vitro* with importin α homologs. Related bipartite NLS sequences are also present in the C-terminus of MFSV and RYSV N proteins, while the analogous regions of the MMV and Taro vein chlorosis virus N proteins contain a monopartite NLS.

The Phosphoprotein (P)

In addition to the chaperone role in maintaining the N protein in soluble form, rhabdovirus P protein is also a co-factor of the L polymerase and a component of the viral NC core (Fig. 2(a)). The SYN V P protein forms complexes *in vivo* with the N and L proteins that are analogous to N-P and P-L complexes found in VSV-infected cells, and also engages in self-interactions that are mediated by the N-terminus of the P protein. Likewise, pairwise N-P and P-P interactions have also been documented for several other plant rhabdoviruses including LYNV, PYDV, and OFV. Rhabdoviral P proteins are highly phosphorylated as their name suggests, and phosphorylation of specific residues play important roles in regulating the P protein activities in transcription and

replication. Direct evidence showing phosphorylation of plant rhabdovirus P protein is available for SYN. In SYN, the P protein is phosphorylated *in vivo* at threonine residues, which differs from the VSV P protein that is phosphorylated at serine residues. Hence, the P proteins of plant rhabdoviruses probably have replication-related functions similar to their well-characterized vertebrate counterparts.

Sequence analyses show that the P proteins of the nucleorhabdoviruses PYDV, RYSV, and MMV carry a NLS, which is consistent with their pronounced nuclear localization patterns. Although similar NLS sequences have not been identified for the SYN and MFSV P proteins, these proteins localize to the nucleus as well as the cytoplasm when transiently expressed in plant cells. Furthermore, the SYN P protein binds directly to human importin β derivatives *in vitro* and the central third of the P protein is required for nuclear import, but other regions of the protein affect the import efficiency. However, co-expression with cognate N proteins relocates the SYN and MFSV P proteins to subnuclear foci exclusively, suggesting that the P proteins may contain a nuclear export signal whose function is masked by the N protein-binding.

Apart from functioning in replication, the P proteins of two cytorhabdoviruses have been shown to exhibit relative weak, yet evident RNA silencing suppressor activities. LYNV P suppresses local RNA silencing and delays systemic silencing. Further mechanistic studies have shown that LYNV P inhibits microRNA-mediated mRNA slicing and transitive RNA silencing likely by interactions with Argonaute (AGO) proteins and the RdRp 6/ Suppressor of Gene Silencing 3 (RDR6/SGS3) complex. Similarly, Alfalfa dwarf virus (ADV) P suppresses local silencing weakly but systemic silencing strongly. ADV P interacts with AGO1 and AGO4, inhibits miRNA-guided AGO1 cleavage and prevents transitive RNA silencing.

The P3 Movement Protein

Like other plant viruses, plant rhabdoviruses encode proteins to assist in cell-to-cell movement of viral infection entities through the plasmodesmata and their systemic transport through the vascular system. Considerable evidence for a movement protein (MP) function has been accumulated for proteins encoded by the gene located between the P and M genes designated P3, whose name varies with viruses, including SYN sc4, LNYV 4b, MFSV P4, PYDV Y, and P3 in most other viruses (Fig. 4). The predicted secondary structures of several plant rhabdovirus P3 homologs have a distant relatedness to structural motifs of the Tobacco mosaic virus 30K superfamily of plant viral MP. Additional evidence for a role of the P3 homologs in cell-to-cell movement is their localizations to the cell periphery or the plasmodesmata and associations with host membranes during transient expression. The movement function for the P3 proteins has been reinforced by *trans*-complementation experiments, in which P3 homologs encoded by various cyto-, and nucleorhabdoviruses, and dichorhviruses have been shown to support cell-to-cell movement of MP-defective positive-strand RNA viruses. In addition, a recombinant SYN sc4 deletion mutant is unable to move from initially infected cells to adjacent tissues, but the movement defect is rescued by transient expression of the sc4 protein *in trans*. Protein interaction experiments revealed that the P3 homologs from SYN, PYDV, RYSV, and Tomato yellow mottle-associated virus (TYMaV) interact with their respective N and/or P proteins, and in the case of SYN sc4, the specific sc4-N and sc4-P interactions appear to facilitate inter- and intracellular NC trafficking. Together, these lines of evidence collectively support a MP role for the plant rhabdovirus P3 proteins.

Protein localization and cellular fractionation assays indicate that several rhabdovirus P3 proteins are membrane-associated, although membrane protein prediction algorithms generally fail to identify any transmembrane regions in these proteins. In addition, SYN sc4 protein was found to be present in purified virions, and after sucrose gradient fractionation, sc4 co-sedimented with the G protein-containing membrane fractions of the virion preparations. Similarly, immunogold labelling has shown that Rice transitory yellowing virus (a strain of RYSV) P3 is also associated with virus particles, but in this case the P3 appears to localize to the interior of the virion in the NC. Thus, these findings provide evidence that plant rhabdovirus MP can also function as structural proteins, but the actual structural role remains obscure.

The Matrix Protein (M)

Within the rhabdovirus particle, the M protein forms a layer connecting the helical NC core and the transmembrane G protein (Fig. 2(a)). During infections, the M protein plays critical roles in virus budding by interacting with the NC core, membrane lipid and the G protein. Studies with vertebrate rhabdoviruses have shown that late in replication, the M protein interacts with genomic NC and directs the condensed core to membrane budding sites that are enriched in viral G protein. Similar functions for plant rhabdovirus M protein are supported by protein localization and interactions studies. The N-M interactions appears to be common among several plant rhabdoviruses including SYN and PYDV. Consistent with the morphogenesis sites of cyto- and nucleorhabdoviruses, the LYNV M protein localizes to the cytoplasm near the cell periphery, but the SYN and PYDV M proteins are targeted to the nucleus. Notably, when transiently expressed in uninfected cells, the SYN and PYDV M proteins distribute uniformly throughout the nucleoplasm; however, in virus-infected cells, the M proteins appear as subnuclear foci bridging the periphery of the inner nuclear membrane (INM) and the viroplasm. These foci likely represent virion maturation sites where coiled NC cores bud through the nuclear membranes.

As with VSV M, the PYDV and SYN M proteins also interact with and remodel host membranes. Infection by SYN, and to a lesser extent by PYDV, results in the formation of intranuclear spherules derived from invagination of the INM (Fig. 5). The spherule formation is also induced when PYDV M is ectopically expressed by itself, and requires a di-leucine motif located at aa

residues 223 and 224 of the M protein. In contrast, expression of SYN V M is insufficient to trigger nuclear membrane rearrangement, and even infection by a recombinant SYN V M deletion mutant fails to induce intranuclear spherule formation. The SYN V M protein requires interactions with the G protein's C-terminal tail to associate with INM and induce membrane remodelling.

In addition to their roles in viral morphogenesis, preliminary experiments indicate that rhabdovirus M proteins have important roles in host–virus interactions because they appear to be able to inhibit host gene expression. The nucleorhabdovirus M protein may also play a role in NC egress from the nucleus. SYN V M protein forms motile foci liberating from the nuclear envelope and moving towards the cytoplasm, whereas PYDV M contains a putative nuclear export signal that may be involved in transport of NC cores into the cytoplasm.

The Glycoprotein (G)

The G protein forms the glycoprotein spikes of rhabdovirus virions (Fig. 2(a)). The plant rhabdovirus G proteins are typical type I membrane proteins, consisting of a signal peptide sequence of ~20 aa, an N-terminal luminal (or virion surface) domain that contains potential glycosylation sites, a transmembrane region followed by a short C-terminal tail. The signal peptide is cleaved by signal peptidases during co-translational translocation to the ER lumen to yield a “mature” transmembrane G protein. In addition, the SYN V G protein contains a putative NLS near the C-terminus that could be involved in transit to the inner nuclear membrane prior to virion morphogenesis. Several glycosylation inhibitors interfere with N-glycosylation of the SYN V G protein and also block SYN V morphogenesis. A prominent role of G protein in morphogenesis is also supported by SYN V reverse genetics studies. A SYN V G protein deletion mutant is abortive in virion maturation, leading to accumulation of striking arrays of naked NC cores that fail to bud through the INM. The C-terminal tail of SYN V G protein is critical for morphogenesis, since this domain is required for relocalization of the M protein to INM surfaces and subsequently membrane remodelling. The N-terminal domain of SYN V G also contributes to efficient budding, but is dispensable for systemic infections.

Although SYN V G protein is not absolutely required for infections of *Nicotiana benthamiana* plant host, a more critical role can be envisioned during infections of insect vectors by analogy to animal rhabdoviruses. The plant rhabdovirus G protein may be crucial for binding to proposed insect midgut receptors and host cell entry. Indeed, antibody blockage or enzymatic digestion of PYDV G protein drastically reduces virus infectivity in insect vector cells.

The Polymerase Protein (L)

The L proteins are the most closely related of the rhabdovirus-encoded proteins and contain conserved mononegavirus polymerase domains and RNA-binding motifs. Alignment of the L protein sequences of non-segmented negative-strand RNA viruses reveals conservation within 12 motifs. Phylogenetic trees derived from L protein alignments indicate that the nucleorhabdoviruses, dichorhavirus and cytorhabdoviruses cluster together in two major clades separated from the vertebrate rhabdoviruses (Fig. 1).

The L proteins of plant rhabdoviruses are present in low abundance within virus particles and in infected cells (Fig. 2(a)). A viral RdRp is activated after treatment of virions of the cytorhabdoviruses LNYV and Broccoli necrotic yellows virus with mild nonionic detergents, and this activity co-sediments with loosely coiled NC filaments that are released from virions. The transcribed products are complementary to the genome, as expected of mRNAs. Thus, the described polymerases of these plant cytorhabdoviruses appear to be similar to the extensively studied polymerases of the vesiculoviruses. In contrast, no appreciable polymerase activity is evident in dissociated preparations of SYN V or other nucleorhabdovirus virions that have been analyzed. However, an active polymerase can be recovered from the nuclei of plants infected with SYN V. Polymerase activity is associated with a complex consisting of the N, P, and L proteins that co-sediments with SYN V NC cores. The polymerase complex can be precipitated with P protein antibodies, but the activity of the complex is not inhibited by these antibodies. However, antibody inhibition experiments demonstrate that the L protein is required for polymerase activity. Kinetic analysis of transcription products also reveals that the complex is capable of sequentially transcribing a polyadenylated plus-sense leader RNA and polyadenylated mRNAs corresponding to each of the six SYN V-encoded proteins. Potential replication intermediates consisting of short incomplete minus-strand products homologous to the genomic RNA are also transcribed. These results thus provide a model whereby nucleorhabdovirus particles require polymerase activation by host components early in infection. In contrast, the polymerases of the cytorhabdoviruses appear to be present in an active form in virions and the released cores are capable of initiating primary transcription immediately upon uncoating *in vitro*.

Other Accessory Proteins

Besides the canonical genes, plant rhabdovirus genomes may also contain 1–4 additional ORFs encoding putative accessory proteins (Fig. 4). For example, an X ORF is present in PYDV and EMDV between the N and P genes, and within the P and M genes, there are 4 ORFs in the two cereal cytorhabdoviruses, *i.e.*, NCMV and BYSMV, instead of only one ORF (P3) in most of the other plant rhabdoviruses. In addition, a short transcriptional unit was found in several cyto- and nucleorhabdoviruses, designated P6 in RYSV, RSMV, ADV, and SCV, and P9 in NCMV and BYSMV. Small ORFs preceding the L gene were also found in the genomes of some animal rhabdoviruses, such as ephemero-, hapa-, and tibroviruses. These ORFs encode small, highly hydrophobic, and basic proteins named viroporins, which function to modify the cell membrane permeability to ions or other small molecules and are

involved in virion assembly and release. The plant rhabdovirus P6 and P9 proteins do not share obvious sequence identity with each other or with the viroporins of animal rhabdoviruses, but some share a characteristic transmembrane domain.

Only very limited information is available regarding the functions of plant rhabdovirus accessory genes. RYSV P6 protein is present in virion preparations purified from infected rice plants and in protein samples from viruliferous leafhoppers, suggesting that P6 has a structural role in infection. RYSV P6 was also shown to suppress systemic RNA silencing by affecting RDR6-mediated secondary siRNA amplification, but did not affect local RNA silencing. However, ADV P6 does not appear to have similar RNA silencing suppressor activities, suggesting that this function is not conserved amongst plant rhabdoviruses.

Cytopathology and Replication

Entry

Little information is available about early entry and uncoating events during plant infections. It is hypothesized that the rigid plant cell wall is breached through insect vector feeding or experimentally by mechanical abrasion, and that the introduced enveloped virions may fuse to cellular membranes to release NC cores into the cytoplasm, followed by M protein disassembly to liberate the flexuous NC filaments. However, during insect vector infections, the surface G proteins of plant rhabdoviruses presumably play a role in binding to proposed midgut receptors that mediate virion uptake into epithelial cells by endocytosis, although such receptors have so far not been identified.

Transcription and Genome Replication

The fundamental replication and transcription processes of plant rhabdoviruses are similar to their animal-infecting counterparts. Cytorhabdoviruses closely resemble animal rhabdoviruses in that both replicate in the cytoplasm, whereas nucleorhabdoviruses and dichorhavirus have exclusive nuclear replication phases (**Fig. 6**). The latter two groups of viruses utilize the host nucleocytoplasmic transport machinery to recognize karyophylic signals present on the N and P proteins to facilitate nuclear targeting of viral core proteins and NC. The plant rhabdovirus replication cycles described below were developed largely by analogy to the VSV model and supported by biochemical characterization of viral polymerase fractions, analyses of viral mRNAs, electron microscopic observations, protein localization and interaction assays, and recent reverse genetics studies.

After NC release from virions, primary rounds of transcription are initiated by using the negative-stranded genome template to produce capped and polyadenylated leader RNA and mRNAs for each of the viral genes. Transcription occurs progressively and sequentially from the genomic 3' end, yielding discrete mRNA species in a decreasing molar gradient, *i.e.*, the mRNA levels follow the order $N > P > P3 > M > G > L$. This sequential and polar transcription is mediated by interactions of the viral polymerase complex with *cis*-regulatory elements located in each gene junction. As primary transcription proceeds, newly synthesized viral proteins increase in abundance. Accumulation of the N and P proteins triggers a switch of the polymerase function from mRNA transcription to genome replication. Upon replication, the viral polymerase initiates antigenomic RNA synthesis at the exact 3' terminus of the genomic RNA and ignores all internal regulatory signals located in the gene junctions. During genome replication, the nascent RNAs are encapsidated by the N-P complex to form antigenomic NC, which then serve as template of the P-L replicase complexes for synthesis of genomic RNAs that are subsequently encapsidated to form genomic NC. Continuous NC formation depletes free N, P, and L proteins, and lower core protein abundances signal a transition from replication to secondary rounds of mRNA transcription to increase the pool of viral mRNAs for replenishment of viral proteins. This cyclic phase of replication and transcription is coordinated by a feedback mechanism that measures the abundance of the core proteins by the levels of nascent leader RNA encapsidation.

Later in cytorhabdovirus replication, accumulation of viral core proteins and progeny NC result in formation of thread-like viroplasms in the cytoplasm that are located in close proximity to dense networks of the ER. Likewise, replication of nucleorhabdoviruses and dichorhavirus induces formation of subnuclear viroplasms in greatly enlarged nuclei that consist of large masses of granular material containing viral RNA and the N, P, and L proteins (**Fig. 2(b)**).

Morphogenesis

The plant rhabdoviruses vary profoundly in their sites of morphogenesis and differ substantially from vertebrate rhabdoviruses that undergo virion maturation at the host plasma membrane. In plant cells, cytorhabdoviruses bud through ER membranes, and mature particles accumulated in ER-associated cytoplasmic cisternae that are greatly proliferated during virus infections. In contrast, the budding of nucleorhabdoviruses, such as SYN and PYDV, occurs in association with the INM, and enveloped virions accumulate in enlarged perinuclear spaces formed between the inner and outer nuclear envelopes (**Fig. 2(b)**; **Fig. 5**). However, dichorhavirus that also replicate in the nucleus do not have an enveloped form of virions. Rather, rod-like non-enveloped particles are present in nuclei of infected cells, either scattered through the nucleoplasm, forming crystalline arrays or arranged perpendicularly onto the INM. Occasionally, these particles are also present in the cytoplasm and appear to be enwrapped by membranous tubular structures. In this case, the virions are arranged radially and perpendicularly to the membrane and form a "spoke wheel" configuration.

Fig. 6 Models for cyto- and nucleorhabdovirus infection cycles in plant cells. Plant rhabdoviruses are initially introduced into plant cells through mechanical breach of the cell wall (CW) during insect vector feeding. Upon entry into the cell, viral nucleocapsids (NC) are liberated from the virions and replication takes place in the cytoplasm (cytorhabdoviruses) or nucleus (nucleorhabdoviruses). For cytorhabdoviruses, the NC initiate primary rounds of transcription in the cytoplasm to yield capped, polyadenylated mRNAs for translation of each viral protein. Primary transcription is followed by genome replication to produce viral antigenomic and genomic RNAs that are encapsidated by the newly synthesized nucleocapsid proteins to form progeny NC, and then by secondary rounds of transcription to increase the pool of mRNAs. As cyclic waves of transcription and replication proceed, accumulation of viral core proteins and NC form cytoplasmic viroplasms (VP). During the later stages of replication, matrix (M) proteins coil NC and likely interact with ER-anchored viral glycoproteins, and morphogenesis occurs by budding of condensed NC into the proliferated ER membranes. Matured bacilliform virions accumulate in pronounced ER vesicles. The replication cycles of nucleorhabdoviruses are fundamentally similar to those of cytorhabdoviruses, but their NC are transported into the nucleus for transcription and replication cycles. The viral mRNAs are exported to the cytoplasm and translated, and the core proteins and M protein are then transported through the nuclear pore complex into the nucleus. As replication progresses, subnuclear VP appear and the nuclei become greatly enlarged. Morphogenesis occurs by budding of coiled NC into inner nuclear membrane (INM), and enveloped virions accumulate between INM and outer nuclear membrane (ONM) of the nuclear envelope (NE). During cell-to-cell movement, the NC exit the nuclei either by a nuclear export activity of a viral core protein or by a “bud-out” process of the enveloped virions. Once in the cytoplasm, the NC of cyto- and nucleorhabdoviruses interact with membrane-associated P3 movement proteins (MP) in a species-specific manner. The MP then direct intracellular NC trafficking to the cell periphery and intercellular movement through gated plasmodesmata (PD) across the CW by mechanisms that may involve microtubule (MT)- and microfilament (MF)-associated host proteins.

Morphogenesis of cyto- and nucleorhabdoviruses occurs during the late stages of replication in which the M protein accumulates and reaches concentrations sufficient to initiate coiling of the genomic NC. The M protein condenses the NC into a compact bacilliform core, which leads to downregulation of RNA synthesis and a transition from replication to virion assembly. The coiled cores are brought to the vicinity of endomembrane surfaces where the transmembrane G proteins are enriched, and then bud through the membranes to acquire lipid envelope and the G proteins. Infections with SYN or PYDV induce massive INM invagination into the nucleoplasm, forming intranuclear spherule-like structures (Fig. 5). This structural rearrangement may function to bring the INM surfaces in close proximity to viroplasms and to provide readily accessible sites for virion maturation.

Cell-To-Cell Movement

A MP function has been assigned to the P3 accessory gene located between the P and M genes for several cyto- and nucleorhabdoviruses, as well as dichorhavirus, since the P3 homologs of these diverse plant rhabdoviruses display cross-family movement *trans*-complementation with positive-strand RNA viruses. Reverse genetics analyses using recombinant SYN

further reinforce that the sc4 protein, a P3 homolog, is essential for SYNIV cell-to-cell movement. The plant rhabdovirus movement complex has been postulated to involve viral NC, since NC constitutes the minimal infectious unit. This hypothesis has been verified by SYNIV reverse genetics studies, which show that SYNIV minigenomes comprising the N, P, sc4, and L genes are capable of autonomous localized movement. Reverse genetics analyses have also revealed a highly specific cell-to-cell movement mechanism for cyto- and nucleorhabdoviruses. The movement defects of MP-deletion mutants of SYNIV and TYMaV can only be rescued by their respective cognate MP, but not by MP from related rhabdoviruses, distantly related or unrelated plant RNA viruses. The movement specificities of SYNIV and TYMaV are explained by the species-specific interactions between NC core proteins and MP.

Available evidence suggests that during replication, some of the newly synthesized NC in the cytoplasm interact specifically with membrane-anchored MP, which facilitate intracellular NC trafficking to the cell periphery, followed by intercellular transport through the plasmodesmata (Fig. 6). Furthermore, NC transport may also involve host cytoskeleton components. Microtubule-associated factors have been identified to interact with MP of SYNIV and LNYV, and actin filaments are required for BYSMV P protein trafficking (Fig. 6). For nucleorhabdoviruses and dichorhavirus that employ nuclear phases of replication, their NC have to be exported from the nuclear replication sites to the cytoplasm before cell-to-cell movement can occur. How the NC nuclear egress is achieved has not been resolved, but this process may involve nuclear exporting function of a viral NC core protein or development of intraluminal virions.

Vector Relationships, Distribution and Evolution

Phylogenetic studies support the general hypothesis that natural host ranges of plant rhabdoviruses are determined by their arthropod vectors more so than by host plant species (Fig. 1). Moreover, where studied, plant rhabdoviruses replicate in cells of their insect vectors as well as in their plant hosts. Taken together, the adaptive evolutionary trajectory of plant rhabdoviruses is likely to be from insects to plants. Plant rhabdoviruses are most frequently transmitted by aphids (Aphididae), leafhoppers (Cicadellidae), or planthoppers (Delphacidae), while dichorhavirus are transmitted by false spider mites (*Brevipalpus* sp.) (Table 1, Fig. 1). The relationship between virus and vector appears to be tightly regulated, given that closely related rhabdoviruses are transmitted by different insect species. This is exemplified by the sanguinolenta and constricta strains of PYDV that are distinguished by their differential transmission by the leafhopper vectors, *Aceratagallia sanguinolenta* and *Agallia constricta*. This relationship occurs in cytorhabdoviruses as well, where Soybean blotchy mosaic virus, for example, has been shown to replicate and persist in its vector, the leafhopper, *Peragallia caboverdensis*. In some cases, plant rhabdoviruses have no known vector, however, phylogenetic clustering of viruses that group according to vector can inform prediction of what type of insect maybe involved in the epidemiology of such viruses (Fig. 1). Importantly, while the virus-insect relationship is constrained tightly, the same rhabdovirus may occur naturally in multiple plant host species. For example, whereas PYDV was once agronomically important on potato, it still occurs in reservoirs of red clover (*Trifolium incarnatum*). Although hampered by the inability to mechanically transmit many plant rhabdoviruses, experimental host ranges have been shown to be substantially broader than those reported from field data. However, in most cases the reservoir species are unknown for this group of viruses, which limits our understanding of their true ecology. Unbiased detection methods, such as RNA-Seq, in wild plant communities are likely to provide significant insight into the population dynamics of rhabdoviruses, and related plant viruses.

Once acquired by the insect vector, it appears that cyto- and nucleorhabdoviruses are persistently transmitted in a propagative manner and can be transmitted to vector progeny, in those cases where this aspect of rhabdovirus biology has been examined. Typical of such relationships, long latent periods (hours to days) are required for virus acquisition before vectors are competent for transmission. Insects remain viruliferous throughout their lives, and transovarial passage through eggs and nymphs has been determined experimentally in some cases. Evidence for tissue tropism of rhabdoviruses is derived from studies with MMV in its planthopper vector *Peregrinus maidis*. Following acquisition from plant tissues, MMV accumulates in the epithelial cells of the anterior midgut, followed by infection of nerve cells. Subsequent infection of tracheal cells, hemocytes, muscles, salivary glands, fat cells, mycetocytes, and, finally, epidermal tissues follows, thus completing the circulative infection cycle. Delivery of MMV by microinjection of *P. maidis* results in efficient virus infection and transmission, facilitating functional virus-vector interaction studies in combination with RNA silencing.

Akin to cyto- and nucleorhabdoviruses, following long periods of acquisition (up to two weeks), dichorhavirus are transmitted in a circulative-propagative manner by *Brevipalpus* mites. Furthermore, transovarial transmission has been reported for a citrus leprosis-associated dichorhavirus. However, to-date vertical transmission of dichorhavirus has not been confirmed. Cytological studies have demonstrated the presence of both viroplasm and particle formation in mites that have fed on plants infected with several dichorhavirus including OFV, Citrus leprosis virus N, Clerodendrum chlorotic spot virus and CoRSV (Fig. 7), suggesting that the ability to replicate in vector tissues is conserved within this group of viruses. As with cyto- and nucleorhabdoviruses, tropism for specific cell types is evident with dichorhavirus, and cells from midgut epithelium and other cell types were shown to have similar cytopathology to that observed in infected plant cells.

There have only been limited studies on the population structures of rhabdoviruses but certain generalities are evident such as the low degree of sequence divergence within populations. Genetic variability studies have been conducted for LNYV, type member of the genus *Cytorhabdovirus*, using the N gene of isolates sampled from both Australia and New Zealand, as well as analyzing symptom expression on *Nicotiana glutinosa*. Sequence analyses supported separation of LNYV isolates into two

Fig. 7 Transmission electron micrograph of a thin section of the midgut of the mite *Brevipalpus phoenicis* collected from bleeding heart (*Clerodendrum x speciosum*) infected by Clerodendrum chlorotic spot virus. Rod-like particles (V) can be seen in the periphery of the nucleus (N), some arranged perpendicularly onto the nuclear envelope (NE). Nearby, a cell of the symbiotic bacterium *Candidatus Cardinium* (Car) can be seen. Courtesy of Prof. E.W. Kitajima, University of São Paulo, Brazil.

subgroups (I and II), with subgroup I predicted to be an older lineage than subgroup II. Interestingly, these subgroups could not be differentiated based on symptom expression in the experimental host *N. glutinosa*. Sub-group I has apparently gone extinct in Australia, presumably due to its less-efficient dispersal in plant reservoir and/or vectors. Similarly, the dichorhavirus CoRSV was found at one hundred percent of locations ($n=45$) sampled in an area spanning 75% of the coffee growing region of Brazil. All cultivars, regardless of cherry color or growth habit, were found to serve as hosts, suggesting that there is limited resistance in commercially deployed germplasm. Phylogenetic analysis based on the N gene identified a strong geo-spatial relationship among isolates, which clustered into three clades, although the overall sequence diversity between isolates was very low. In contrast to LNYV, and despite low genetic diversity among isolates, variation in symptom expression of CoRSV infection was observed in the experimental host *Chenopodium quinoa*. Based on these studies the hypothesis that the spread of CoRSV is constrained by the clonal expansion of thelytokous populations of *B. papayensis* has been proposed. Further studies, particularly in reservoir host species, once identified, are required to determine if population structure observed in the agronomic hosts holds across a broader range of hosts. While the distribution of most dichorhviruses appears to be limited to South America, OFV has a global distribution.

Glossary

Albetovirus *Al-* for alphacrovirus [helper virus], *be-* for betanecrovirus [helper virus], *to-* for tobacco.

Aumaivirus *Au-* for aureusvirus [helper virus], *mai-* for maize.

Hyperparasite A parasite whose host (in this article, a helper virus) is also a parasite.

Papanivirus *Pa-* for panicovirus [helper virus], *pani-* for panicum.

Satellite RNA A subviral RNA genome dependent on a helper virus for both replication and encapsidation.

Satellite virus A polyphyletic group of viruses encoding structural components of their virions, but incapable of completing the infection cycle without the assistance of a helper virus.

Virtovirus *Vir-* for virgavirus [helper virus], *to-* for tobacco.

Introduction

Viruses span an entire range of morphological, genomic, and functional complexity. Some viruses are exceedingly complex, surpassing many unicellular organisms in terms of physical dimensions and genome sizes. For instance, members of the family *Mimiviridae* carry megabase-sized genomes and encode over 1000 proteins, including many molecular machineries required for virus multiplication. On the other side of the complexity spectrum are viruses carrying just one or two genes, suggesting a stronger reliance on the host compared to the bigger viruses. Notably, some viruses depend not only on the host cells but also on other viruses for reproduction.

The phenomenon whereby one virus depends for its propagation on another virus has been first described in a plant virus system in the early 1960s. Certain preparations of tobacco necrosis viruses (TNV; genera *Alphanecrovirus* and *Betanecrovirus*, family *Tombusviridae*) contained two types of spherical particles that differed in size and antigenic properties. The larger, TNV, particles could propagate autonomously, whereas the smaller ones were unable to replicate in the absence of TNV. The smaller particles became known as particles of satellite tobacco necrosis virus (STNV), whereas TNV is referred to as STNV's helper virus. Subsequently, several other plant viruses having features similar to those of STNV have been discovered. Furthermore, viruses which depend on another virus for reproduction have been described in protists and animals. Overall, satellite viruses vary considerably in terms of complexity and evolutionary origins. Also, the functions supplemented by the helper viruses vary from one virus system to another. For instance, satellite viruses of plants rely on helper viruses for genome replication, whereas members of the *Lavidaviridae* depend on giant mimiviruses for transcription, clearly indicating that satellite viruses have evolved on several independent occasions.

The tripartite relationship between satellite viruses, helper viruses and host cells is an example of hyperparasitism, which is not uncommon in complex natural ecosystems. Indeed, there are other genetic elements which parasitize viruses, most notably, including satellite nucleic acids. The key difference between satellite nucleic acids and satellite viruses is that the latter necessarily encode components of their virions, whereas the former do not. Instead, satellite nucleic acids commonly encode proteins responsible for the replication of the cognate nucleic acid, whereas the components of the virion for horizontal transfer between the hosts are being provided by the helper viruses.

Due to their dependency on other, quasi-autonomous viruses for reproduction, most satellite viruses, with a notable exception of members of the genera *Dependoparvovirus* and *Deltavirus*, have been for a long time considered as sub-viral agents and not officially classified by the International Committee on Taxonomy of Viruses (ICTV). However, in 2016, the arbitrary distinction between satellite viruses and other viruses has been abandoned and satellite viruses were incorporated into the ICTV classification scheme, resulting in establishment of several genera and families. Plant satellite viruses have been classified into genera *Albetovirus*, *Aumaivirus*, *Papanivirus*, and *Virtovirus*; family *Sarothroviridae* has been created for classification of positive-sense (+)RNA satellite viruses that infect arthropods, and *Lavidaviridae* includes double-stranded DNA viruses replicating in protist cells and parasitizing giant viruses of the family *Mimiviridae*.

This article describes the diversity and properties of plant satellite viruses belonging to the genera *Albetovirus*, *Aumaivirus*, *Papanivirus* and *Virtovirus*.

Fig. 1 Plant satellite viruses. Structural similarity between the virions and jelly-roll capsid proteins of satellite tobacco necrosis virus (STNV; PDB ID: 2BUK), satellite panicum mosaic virus (SPMV; PDB ID: 1STM) and satellite tobacco mosaic virus (STMV; PDB ID: 4QQ8). All three virions have $T = 1$ icosahedral symmetry. Images of the depicted virions were downloaded from the VIPERdb database (viperd.b.scripps.edu/). Genome maps of the three viruses are shown at the bottom with the gene encoding the capsid protein shown in blue.

Albetoviruses: Viruses Related to Satellite Tobacco Necrosis Virus

STNV is one of the most extensively studied satellite viruses. Over the years, many properties of this virus, including its genome sequence, virion structure and mechanism of capsid assembly, as well as details of the interaction with the helper virus, have been elucidated. The linear positive-sense (+)RNA genome of STNV consists of 1239 nt and encodes a single jelly-roll-fold capsid protein (CP) of 195 aa, which is necessary and sufficient for formation of icosahedral ($T = 1$) virions (Fig. 1). Virion assembly proceeds cooperatively via interactions between the packaging signals, degenerated stem-loop structures distributed throughout the genome, and multiple CP copies.

In the natural habitat, STNV is transmitted through the soil the same way as its helper virus, i.e., by zoospores of a plant-pathogenic fungus *Olpidium brassicae*, suggesting that both viruses share certain transmission determinants. For both TNV and STNV, the 5' ends of the genomes are phosphorylated and lack a 7-methylguanylate cap or a genome-linked protein, whereas the 3'-termini lack a polyadenylation sequence. Several *cis*-acting elements located within the 5' and 3' untranslated regions (UTRs) are responsible for efficient translation and replication of the STNV genome. The 3' and 5' UTRs of STNV and TNV can be exchanged without abolishing RNA accumulation, although the translation elements at the 3'-terminal regions appear to be unrelated in the two viruses.

Three serotypes of STNV have been described: STNV-1 (or STNV), STNV-2, and STNV-C (Table 1). Different STNV strains are activated by different helper viruses. The replication of STNV-1 and STNV-2 is supported by isolates of TNV-A, the sole member of the *Tobacco necrosis virus A* species (genus *Alphanecrovirus*), whereas TNV-D, the sole member of the *Tobacco necrosis virus D* species (genus *Betanecrovirus*), supports the replication of STNV-C. Genome sequences and organizations for the three STNV strains are overall similar (Table 1). CPs are $\approx 50\%$ – 63% identical in sequence. Whereas the 5' UTRs of STNV-1 and STNV-2 are 30 nt in length and are nearly identical, the corresponding region in STNV-C is considerably longer (101 nt). Similarly, whereas the 3' UTRs of STNV-1 and STNV-2 approximately 64% similar to each other, they share only 40% and 38% identity to that of STNV-C.

STNV-like viruses STNV-1, STNV-2, and STNV-C are classified into three species, *Tobacco albetovirus 1*, 2, and 3, respectively, within a genus *Albetovirus* (sigil: *Al-* for *al*phanecrovirus [helper virus], *be-* for *be*tanecrovirus [helper virus], *to-* for *to*bacco).

Aumavirus: Satellite Maize White Line Mosaic Virus

The fourth, more divergent member of the STNV-like virus group is satellite maize white line mosaic virus (SMWLMV; Table 1). SMWLMV depends on maize white line mosaic virus (MWLMV; species *Maize white line mosaic virus*, genus *Aureusvirus*, family *Tombusviridae*) for multiplication. MWLMV can infect maize in the absence of SMWLMV, whereas the same is not true for SMWLMV, which replicates in maize only when co-inoculated with MWLMV. The ssRNA genome of SMWLMV is 1168 nt in length and encodes one CP (Table 1). Similar to STNV-like viruses, the SMWLMV virion is 17 nm in diameter. SMWLMV CP displays 32% identity to the CP of STNV-1, strongly suggesting that SMWLMV and the STNV-like viruses have diverged from a common ancestor. However, due to lower sequence similarity between the CPs of STNV-like viruses and SMWLMV, the latter virus has been classified into a species, *Maize aumavirus 1*, within a separate genus *Aumavirus* (sigil: *Au-* for *au*reusvirus [helper virus], *mai-* for *mai*ze).

Papaniviruses: Viruses Related to Satellite Panicum Mosaic Virus

Satellite panicum mosaic virus (SPMV) depends on Panicum mosaic virus (PMV; species *Panicum mosaic virus*, genus *Panicovirus*, family *Tombusviridae*) for replication as well as systemic spread in plants. The 5'-terminus of the SPMV genome is phosphorylated and lacks a 7-methylguanylate cap. Several secondary structure elements implicated in the replication of the SPMV genome were

Table 1 General properties of plant satellite viruses

Satellite virus	Species	Helper virus	Accession #	Genome, nt	Capsid Ø, nm	Comments
<i>Albetovirus</i>						
Satellite tobacco necrosis virus (STNV-1)	<i>Tobacco albetovirus 1</i>	tobacco necrosis virus A (<i>Tombusviridae</i>)	V01468	1239	17	STNV suppresses the replication of its helper virus and ameliorates the TNV-induced symptoms in different hosts
Satellite tobacco necrosis virus 2 (STNV-2)	<i>Tobacco albetovirus 2</i>	tobacco necrosis virus A (<i>Tombusviridae</i>)	M64479	1245	17	STNV and STNV-2 coat protein genes share 55% nucleotide sequence identity, whereas the UTRs are more similar
Satellite tobacco necrosis virus C (STNV-C)	<i>Tobacco albetovirus 3</i>	tobacco necrosis virus D (<i>Tombusviridae</i>)	AJ000898	1221	17	STNV and STNV-C coat proteins share 62% sequence identity, whereas the 3'UTRs are only 40% identical
<i>Aumavirus</i>						
Satellite maize white line mosaic virus (SMWLMV)	<i>Maize aumavirus 1</i>	maize white line mosaic virus (<i>Tombusviridae</i>)	M55012	1168	17	CP is 32% identical to that of STNV-1
<i>Papanivirus</i>						
Satellite panicum mosaic virus (SPMV)	<i>Panicum papanivirus 1</i>	Panicum mosaic virus (<i>Tombusviridae</i>)	M17182	826	16	Besides virion formation, CP of SPMV has several other biological functions, including systemic accumulation, maintenance and movement of the SPMV RNA
Satellite St. Augustine decline virus (SSADV)	<i>Panicum papanivirus 1</i>	St. Augustine decline virus strain of PMV (<i>Tombusviridae</i>)	L10083	824	ND	SSADV is a strain of SPMV (36 nt substitutions; 5 aa changes)
Satellite grapevine virus (SGVV)	unclassified	grapevine virus F (<i>Betaflexiviridae</i>)?	KC149510	1060	ND	SGVV and GVF share stem-loop structures at the 5' ends of the genomes
<i>Virtovirus</i>						
Satellite tobacco mosaic virus (STMV)	<i>Tobacco virtovirus 1</i>	tobacco mosaic virus (<i>Virgaviridae</i>)	M25782	1059	17	The 3'UTR is similar to that of tobamoviruses, with a clear sequence similarity between STMV and TMV

predicted in the 5' and 3' UTRs. The 826 nt-long ssRNA genome of SPMV contains two open reading frames (ORF; [Table 1](#)). However, only one of them (the one encoding CP) is expressed in *in vitro* translation assays.

The sequence of SPMV CP is not appreciably similar to those of STNV-like viruses (below 15% identity). However, X-ray structure analysis of the SPMV particle revealed that the protein has a similar jelly-roll fold as the corresponding protein of STNV ([Fig. 1](#)). Beside its structural role, SPMV CP has several other biological functions, most notably, systemic accumulation, maintenance, and movement of the cognate SPMV RNA in plants. Interestingly, the latter activities of SPMV CP apparently extend to the helper virus RNA, assisting in its maintenance or stabilization. It is noteworthy that PMV and SPMV are involved in a peculiar tripartite association with a 350 nt-long satellite RNA (satRNA), whereby PMV provides necessary factors for satRNA replication and SPMV provides CPs for satRNA encapsidation.

Two other viruses encoding SPMV-like CPs have been reported ([Table 1](#)). The first one, satellite St. Augustine decline virus (SSADV), is associated with the St. Augustine decline strain of PMV. SSADV is 95% identical to SPMV over the entire genome length (36 nt changes, 5 aa changes) and is considered as a different strain of SPMV rather than a different species. Notably, SSADV genome is 2 nucleotides shorter than that of SPMV, making it the shortest known satellite virus genome ([Table 1](#)). The second putative satellite virus, satellite grapevine virus (SGVV), has been discovered by deep sequencing of total genomic RNA from grapevine. However, neither the viral particles nor the associated helper virus have been characterized. SGVV CP shares ≈24% sequence identity with SPMV CP.

SPMV and SSADV have been assigned into a genus *Papanivirus* (sigil: *Pa-* for panicovirus [helper virus], *pani-* for panicum), within a species *Panicum papanivirus 1*. By contrast, SGVV remains unclassified due to lack of information on its ability to form virions as well as on the identity of its helper virus.

Interestingly, homologs of SPMV CP are encoded by certain satRNAs. In particular, bamboo mosaic virus satellite RNA (satBaMV; 836 nt) encodes a protein (P20) which is 44% identical to the CP of SPMV. P20 plays a role in the accumulation and movement of the satBaMV but does not participate in satRNA encapsidation. Instead, satBaMV is packaged into rod-shaped particles by the CP of the helper bamboo mosaic virus, a member of the family *Alphaflexiviridae*. In addition, a sequence of olive viral satellite RNA (OVsatRNA) has been deposited to GenBank that encodes a protein 35% identical to P20 of satBaMV. Considering the conservation of the SPMV-like CPs, it appears likely that satBaMV and OVsatRNA have evolved from genuine

satellite viruses, once again emphasizing the apparent ease with which transitions between different types of mobile elements (i.e., parasitic nucleic acids and viruses) occur.

Virtovirus: Satellite Tobacco Mosaic Virus

Satellite tobacco mosaic virus (STMV) has been isolated from *Nicotiana glauca* (tree tobacco) and is naturally associated with and dependent on tobacco mild green mosaic virus (TMGMV; species *Tobacco mild green mosaic virus*, genus *Tobamovirus*, family *Virgaviridae*). However, under experimental settings, STMV can adapt and replicate in many plant hosts (e.g., tobacco, pepper, tomato) in association with other tobamoviruses, including tobacco mosaic virus (TMV). The adaptation of STMV to other helper viruses involves the deletion of a single G residue in a stretch of five G residues (positions 61–65) in the 5' UTR, together with a change in the 5' nucleotide. Thus far, STMV is the only known satellite virus that uses rod-shaped viruses as helpers.

The STMV genome is a linear ssRNA molecule of 1059 nt that contains two ORFs (Fig. 1), both of which are functional in the *in vitro* translation assay. The first ORF encodes a protein of 58 aa which lacks similarity to proteins in the public databases and appears to be dispensable for STMV multiplication. Indeed, certain naturally occurring isolates of STMV contain a deletion within ORF1 and do not produce the corresponding product. The second ORF encodes STMV CP, which also has no identifiable homologs in sequence databases. However, structural analysis shows that the STMV CP has a jelly-roll fold similar to those of STNV and SPMV (Fig. 1), suggesting that the three satellite viruses might be evolutionarily related.

As in the case of STNV and SPMV, but different from the helper TMV virus, the genome of STMV lacks a 7-methylguanylate cap and the first 6 nt of the STMV RNA are identical to those of the STNV genome. However, in contrast to STNV and SPMV, the 5' end of STMV genome is not phosphorylated. The 3' UTR is predicted to contain a series of pseudoknots followed by a tRNA-like structure which can be amino acylated with histidine. The latter features are strikingly similar to those of the genome of helper TMV and other tobamoviruses, with 40–50 nt-long regions of near identity among the STMV and TMV 3' UTRs. These secondary structure elements play critical roles in STMV genome replication, translation, and initiation of virion assembly.

STMV is currently a sole representative of the species *Tobacco virtovirus 1* within the genus *Virtovirus* (sigil: *Vir-* for virgavirus [helper virus], *to-* for tobacco).

Effect of Mixed Infections on the Host and the Helper Viruses

The parasitic lifestyle of satellite viruses is usually associated with negative effects on the fitness of the helper virus, whereas the effect on the host cell during a co-infection might differ drastically between viruses. The negative effect of STNV on the propagation of its helper virus manifests as a decrease in (1) the number of necrotic lesions formed in co-inoculated plant leaves, (2) diameter of the lesions, and (3) the amount of TNV produced in inoculated leaves. However, several factors influence the extent to which TNV multiplication is affected. In particular, these include the relative concentrations of the satellite and helper viruses in the inoculum, the physiological state of the host plants before and during the infection, and the type of plant used for the assay. An excess of STNV present during co-infection reduces the yield of TNV to non-detectable levels. This reduction is associated with a selective decrease in the synthesis of TNV capsid protein, suggesting that STNV affects TNV virion production. By contrast, co-infection of PMV with SPMV exacerbates PMV disease phenotype in millet plants resulting in a severe chlorosis and stunting, reduced seed production, and often death of the infected plant. The synergism between PMV and SPMV is also characterized by the more rapid systemic accumulation of PMV and SPMV CPs and genomic RNAs than during infection by PMV alone. Expression of the SPMV CP from a potato virus X-based vector was shown to induce the formation of chlorotic spots on the host as well as non-host plants, confirming that SPMV CP is a pathogenicity determinant.

The effects of STMV on the multiplication of its helper virus, as well as on the helper virus-induced symptoms, are dependent on the host. In tobacco plants, STMV does not change the mild mosaic symptom caused by TMGMV, whereas in jalapeno pepper severe leaf blistering induced by TMGMV is attenuated by STMV infection. Furthermore, tobamovirus titers are greatly decreased by STMV in pepper compared to other hosts.

Common Ancestry of Plant Satellite Viruses?

Plant satellite viruses from the four groups described above all propagate in flowering plants (angiosperms) and share several genomic and structural characteristics that distinguish them from other known viruses. Namely, representatives of all four satellite virus groups form capsids with $T = 1$ icosahedral symmetry and composed of 60 CP subunits (Fig. 1). Although common among ssDNA viruses (e.g., nanoviruses and circoviruses), $T = 1$ capsids are not used by other known ssRNA viruses, which typically have larger $T = 3$ or $T = 4$ capsids. Furthermore, the CPs of all described plant satellite viruses have the same jelly-roll fold (Fig. 1), despite negligible sequence similarity. The similarities also extend to the genomic characteristics. In particular, in all plant satellite viruses, the linear ssRNA genomes lack the 5' 7-methylguanylate caps and polyadenylation sequences in their 3' UTRs. Furthermore, 5' ends of the STNV and SPMV genomes are phosphorylated, whereas the first six

nucleotides at the 5'-terminus of the STMV genome are identical to those in STNV. Considering these similarities, it is conceivable that all plant satellite viruses have evolved from a common ancestor. Notably, in structural comparison of the satellite virus CPs with the jelly-roll CPs of other viruses, satellite viruses formed a monophyletic clade, indicating that they indeed might share a common ancestor, despite high sequence divergence.

Concluding Remarks

Due to their simplicity, satellite viruses have served (and continue to serve) as useful models for elucidating the molecular details underpinning various processes, including mechanisms of cap-independent protein translation, virion assembly and viral genome encapsidation. For instance, it has been recently demonstrated that assembly of the icosahedral STNV virion proceeds through recognition of the packaging signals on the viral RNA by the CP, which promotes the protein-protein interactions needed to build the capsid. Similar virion assembly mechanism has been also validated for more complex ($T = 3$) bacterial and animal ssRNA viruses, underscoring the relevance of satellite viruses as model systems. Plant satellite viruses also provide a window into the complexity of natural ecosystems, where "one-on-one" virus-host encounters are likely to be rare, but rather involve multiple viruses and other types of genetic parasites interacting in an antagonistic or synergistic manner depending on environmental as well as virus- and host-specific cues. Thus, further studies on tripartite host-virus-satellite virus systems are likely to reveal new facets of virus-host and virus-virus interactions. Finally, despite their minimalism, the ultimate origins of satellite viruses remain enigmatic. On the one hand, it is possible that plant satellite viruses resemble the simplest, potentially ancestral, RNA viruses, which could have existed at the early stages of the evolution of the virosphere. On the other hand, it cannot be excluded that they are a result of reductive evolution from more complex quasi-autonomous RNA viruses. Further exploration of satellite virus diversity in other plants and animals should shed light on the evolutionary origins of this remarkable group of viruses.

Polyacrylamide gel electrophoresis (PAGE) An analytical method for separating biological macromolecules (proteins or nucleic acids) by size and charge.

Sharka disease Sharka means pox in Bulgarian, as such symptoms on fruits were first observed in this country.

Introduction

Plum pox virus (PPV), the agent responsible for the Sharka disease, belongs to the genus *Potyvirus* (family *Potyviridae*). The natural host range of this virus is restricted to *Prunus* spp. (stone fruits and ornamental trees). The infection of susceptible genotypes results in characteristic foliar and fruit symptoms and premature fruit drop. The geographical distribution covers the vast majority of *Prunus* producing area (except Australia, New Zealand, South Africa and the USA), although with widely different incidence levels in different countries. PPV is transmitted non-persistently by more than 20 aphid species, by grafting and vegetative multiplication of infected plants, but is not seed-borne. To date, at least 10 strains/molecular groups of PPV have been identified based on biological, serological, and molecular properties (M, D, Rec, EA, T, W, C, CR, CV and An). Although many diagnostic tools are available for the sensitive and/or specific detection of PPV, its huge variability, uneven distribution in infected woody hosts and its low titre outside of the active growth period significantly complicate its detection. In regions free of PPV, strict quarantine measures are usually enforced.

With the limited availability of resistant or tolerant fruit tree varieties, a mix of prophylactic approaches including the use of virus-free propagation material, eradication of diseased trees, and vector control is generally used in an effort to control the virus in regions where it has not reached an endemic status.

Economical Importance

PPV is considered as the most detrimental viral pathogen of stone fruit *Prunus* crops (peach, apricot, plum, Japanese plum). The disease is named according to the characteristic symptoms on fruits (sharka means pox in Bulgarian, as it was first observed in this country). During approximately a century of recognized existence, PPV has had a devastating impact on the global stone-fruit industry and nursery production, mainly in the central and south European countries. The damages are linked not only to the direct fruit yield and quality losses, but include also quarantine, eradication, prevention and compensatory measures. Since the 1970s the global negative impact of PPV has been estimated to exceed 10 billion euros.

In the field, *Prunus* trees infected with PPV cannot be cured and are often eliminated as a consequence of disease eradication or containment efforts. PPV infected trees are usually not stunted and do not die, however, the infection is manifested by pronounced symptoms negatively affecting fruit yield and quality. The fruits of susceptible *Prunus* hosts are in some cases unsuitable for consumption or processing because of decreased weight and sugar content, overall lower gustative quality and visual defects (depressions, flesh browning, necrosis or gumming). The most spectacular symptom is the premature fruit drop, which may reach 80%–100% in the most susceptible cultivars. Consequently, traditional susceptible cultivars have in many places been replaced by less susceptible or tolerant cultivars, which are often of lower gustatory quality.

The economic losses are not only associated with fruit production, but PPV also negatively affect the production of propagation materials (rootstock, budwood, scions) as in case of contamination these cannot be commercialized. Because of its high potential impact on stone fruit crops, PPV has been included in a list of the top ten plant viruses for impact or scientific interest and is listed as a quarantine pathogen in many parts of the world. In Europe for example, PPV is listed in the EC Plant Health Directive (Annex II of the European Union council directive 2000/29/EEC).

History and Geographical Distribution

The sharka disease was observed for the first time around 1917 on plum cv. Kyustendil in the village of Zemen in western Bulgaria, near the Yugoslavian border. The viral character of the disease on plum and on apricot was described in 1933. Later, PPV was recognized on peach (in the 1960's) and on cherries (in the 1980's). Mainly after World War II, sharka was gradually reported in

various *Prunus* species from different regions across the European continent and Mediterranean basin and later from other continents. Although these reports and their timescale do not necessarily represent the actual dissemination events, they suggest a progressive spread of PPV, probably through infected propagation material. Apart from the widespread distribution in Europe, the virus has been reported from South American (Chile, Argentina), the North American continent (USA, Canada), Asia (China, Japan, Asia Minor) and North Africa (Egypt, Tunisia).

However, its prevalence varies from region to region from the endemic occurrence observed in central and eastern European countries, where the virus is well established, to local and more limited incidence observed in other countries where the virus was only introduced recently or where strict phytosanitary control measures have been enforced and have successfully kept the virus under some level of control (e.g., USA, where eradication was recently achieved).

Host Range and Symptomatology

The natural host range of PPV is restricted to species of the genus *Prunus* (family *Rosaceae*), including cultivated stone fruits – plum (*P. domestica*), Japanese plum (*P. salicina*), apricot (*P. armeniaca*), peach and nectarine (*P. persica*), almond (*P. dulcis*) and myrobalan (*P. cerasifera*). Sweet cherry (*P. avium*), sour cherry (*P. cerasus*) and mahaleb cherry (*P. mahaleb*) can also be naturally infected by cherry-adapted PPV isolates.

PPV also infects wild and ornamental species, such as nanking cherry (*P. tomentosa*), Japanese apricot (*P. mume*), Canadian plum (*P. nigra*), American plum (*P. americana*), dwarf flowering almond (*P. glandulosa*), and blackthorn (*P. spinosa*), which may thus act as local reservoirs of the virus.

Symptoms on *Prunus* trees may be observed on leaves, flowers, fruits, and/or stones, however, they vary depending on host/cultivar susceptibility, virus isolate, physiological status and age of the host and environmental conditions (Fig. 1). The presence of other viruses in the trees, such as *Prunus* necrotic ringspot virus (PNRSV), prune dwarf virus (PDV) or apple chlorotic leafspot virus (ACLSV) may further increase the severity of symptoms.

Under field conditions, the symptoms on *Prunus* plants are often masked late in the season or during the warm period of the growing season. Also, early infections are often characterized by symptoms restricted to only some parts of tree canopy and full systemic invasion of a tree may require several years. These factors may complicate in some cases the identification of the disease by visual inspection. Moreover, the irregular distribution and translocation of the virus in the trees and the low titre outside the active growth period may complicate the detection of the virus when methods of insufficient sensitivity are used.

Typical foliar symptoms on plum consist generally of pale green chlorotic rings, spots, or patterns. Susceptible cultivars develop shallow ring or arabesque depressions on fruits, sometimes with brown or reddish necrotic flesh and gumming. Tolerant plum cultivars show no symptoms on fruits.

Infected apricots develop chlorotic or pale-green rings and lines on leaves, light-colored depressed rings on fruits, which may be severely deformed. Stones are marked with typical discolored rings.

Symptoms on susceptible peach genotypes are pronounced vein clearing, small chlorotic blotches, and distortions of the leaves. Color-breaking symptoms on the petals are observed in some varieties. Pale rings or diffuse band are visible on the skin of the fruits. In general, the symptoms on peach tend to be less visible in comparison to those on plums and apricots. Infection of almond is often symptomless or with limited foliar symptoms.

Characteristic symptoms on cherries consist of pale green patterns and rings on leaves. Fruits may be slightly deformed, with chlorotic and necrotic rings and notched marks.

Premature drop of fruits (reaching up to 100% in the most susceptible cultivars) is frequently observed, particularly in plum and apricot.

Virion Structure and Genome Properties

The flexuous filamentous viral particles are approximately 750 × 15 nm. Viral particles are composed of the single-stranded genomic RNA encapsidated by a single type of capsid protein subunit. The genome is of positive polarity and is 9741–9795 nt in length. It has a polyadenylated 3' end and a virus-encoded protein (VPg) covalently bound at its 5' end. The genomic organization is typical of potyviruses, with a single open reading frame encoding a large polyprotein precursor (3125–3143 amino acids, c. 355 kDa) that is proteolytically processed by three virus encoded proteinases (P1, HC-Pro, and NIa-Pro) to yield as many as ten mature functional proteins. As in other potyviruses, an additional product, P3N-PIPO, produced by a polymerase slippage mechanism from an alternative short ORF embedded within the P3 coding sequence, has been predicted (Fig. 2).

Strains/Molecular Groups

Initial attempts to study PPV variability involved the description of symptoms observed following mechanical inoculation of susceptible experimental herbaceous hosts. The most widely used biological classification system resulting from these efforts was based on the reaction of an experimental local-lesion host, *Chenopodium foetidum*, and PPV isolates were assigned as yellow, intermediate, and necrotic types depending on the type of local lesions they induced. It was also observed that different isolates

Fig. 1 Typical leaf and fruit symptoms caused by Plum pox virus infection on susceptible *Prunus* genotypes, i.e., plum (*P. domestica*) (a, b, f), apricot (*P. armeniaca*) (c, d) and peach (*P. persica*) (e).

can induce variously severe symptoms on some woody indicators (*Prunus persica* GF305, *P. tomentosa*) after chip budding or controlled aphid transmission.

However, such phenotypic characterization efforts remained often unreproducible because of difficulties to standardize the assays and of the influence, at least to some extent, of environmental conditions. Moreover, these experiments did not establish the link between these biological properties and the serological/molecular properties of PPV isolates.

In the late 1970s, the existence of two serogroups of PPV was demonstrated using agar double diffusion assays employing polyclonal antibodies and a purified, formaldehyde-treated, suspension of undegraded viral particles. These two serogroups were named M and D, after the first inoculum sources used in these experiments (Marcus from peach in Greece and Dideron from apricot in south-eastern France, respectively).

Fig. 2 Schematic representation of the Plum pox virus genome (A). The viral polyprotein and the alternative PIPO small ORF are represented by oval rectangles divided into boxes representing the respective functional products with their deduced length in amino acids (based on the AY028309 isolate). Polyprotein processing (B) by the three viral-encoded proteinases to yield the mature viral proteins. PIPO is expressed by a frameshifting resulting from a polymerase slippage mechanism.

It was later shown that different PPV isolates, belonging to these two serogroups (recognized as strains), show also reproducible coat protein (CP) mobility differences in denaturing polyacrylamide gel electrophoresis (PAGE) as well as a strain-specific *Rsa* I restriction site polymorphism in the region encoding the CP carboxy-terminus (CP C-terminus). However, some rare isolates behaved unusually using this RFLP typing assay, indicating that the serological and/or molecular variability of PPV is wider than that observed in these two D and M strains.

Indeed, on the basis of recent molecular analysis, at least 10 strains of PPV, grouping isolates sharing common molecular (and, partially, serological) properties are now recognized. This classification has been validated by comparisons of complete genomic sequences of representative isolates for each of these strains.

Although isolates of each strains were initially thought to have also in common some biological and epidemiological properties, such shared characteristics are now understood to exist only in some strains, and to be limited by the high intra-strain biological variability of PPV. Most PPV isolates can be assigned to one of the three major strains (PPV-M, D and Rec). Other strains are geographically limited PPV-W, EA and T, cherry adapted strains PPV-C, CR and CV and the atypical PPV-An strain.

PPV-M (named after the type isolate Marcus). The isolates of this strain are present in many European countries, but absent from the Americas and China. They are often associated with rapidly spreading epidemics in peach but are less frequently found on plums. Usually, PPV-M isolates are transmitted efficiently by aphids. A high intra-strain molecular diversity was recently confirmed in PPV-M by the identification of divergent PPV-M-Ist isolates from Turkey.

PPV-D (named after the type isolate Dideron). Based on geographical distribution data, PPV-D seems to be the most successful strain as PPV-D isolates are widespread in all areas where PPV has been reported, including the recent outbreaks in Asia and South and North America. PPV-D isolates naturally infect all the susceptible *Prunus* species excluding cherries, but are less frequently associated with spreading epidemics in peach.

PPV-Rec (from "recombinant"). This group of isolates was recognized through the use of improved strain-typing methods targeting different genome portions. PPV-Rec genomes are characterized by a conserved homologous recombination event between PPV-M and PPV-D-like sequences, with a cross-over located in the 3' terminal part of the NIb coding region. PPV-Rec is therefore unrecognisable from PPV-M when using CP-based serological tests. Therefore, a number of isolates originally described as PPV-M were later retyped as belonging in fact to the PPV-Rec strain. PPV-Rec isolates are widespread in several central and eastern European countries, frequently associated with plums and efficiently transmitted by aphids. Interestingly, natural infections of peach by PPV-Rec are rare and mostly symptomless.

PPV-W (from "Winona"). Although the first PPV-W report is from a few infected plum trees in Canada, the probable origin of this strain can be placed in Eastern Europe. PPV-W isolates were found naturally spreading and disseminated in different *Prunus* in Russia, Latvia and Ukraine. The Canadian PPV-W isolate shows multiple recombination events in its genome, one of which is absent in the genomes of East European PPV-W. PPV-W shows the highest intra-strain variability. PPV-W isolates are efficiently transmitted by aphids. Although not reported from central or western Europe, PPV-W isolates are competitive with the main strains in their regions of occurrence.

PPV-EA (named after the type isolate El Amar) was originally isolated from apricots in the El Amar region of the Nile delta in Egypt in the late 1980s. It has also been observed in peach and in other regions of Egypt but has thus far not been reported outside this country.

PPV-T (from "Turkey"). Found widespread in Turkey and also reported from Albania, PPV-T isolates are characterized by a unique recombination event affecting the 5' part of their genome.

PPV-C (from "Cherry") was first reported on sour cherry in Moldova and on sweet cherry in Italy. This group of cherry-adapted isolates has until now been sporadically reported from some central and eastern European countries, apparently without an epidemiological significance. PPV-C isolates are aphid transmissible and systemically infect sweet and sour cherry and *P. mahaleb*, however, they can also infect other *Prunus* species under experimental conditions.

PPV-CR (from "Cherry Russian") is the second strain naturally infecting cherries, although molecularly distinct from PPV-C. The PPV-CR isolates were found in two geographically distant areas of European Russia (Moscow and Samara regions). Similarly, to PPV-C, the isolates of this strain can be experimentally inoculated to other *Prunus* species and are transmitted by aphids.

Fig. 3 Phylogenetic relationships of strains of PPV. (A) Unrooted phylogenetic tree computed using full-length genome sequences (available in the GenBank database, accessed on March 2019) showing the relationships between isolates of all ten recognized PPV strains. (B) Pairwise genetic distances calculated on the full-length genomes of representative isolates of all ten recognized PPV strains. The representative isolates are identified by their Genbank accession numbers.

PPV-CV (from “Cherry Volga”) is the third cherry-adapted strain of PPV, identified recently on sour cherries in the Tatarstan region (middle Volga river region of Russia). The sequence identity between PPV-CV isolates and those of other cherry-adapted strains (C, CR) reaches only ca. 83%, clearly separating them in phylogenetic analyzes into distinct monophyletic groups. Due to their restricted geographical dissemination and recent discovery, the epidemiological importance of these strains for cherry production remains to be determined. Cherry-adapted strains calculated intra-strain diversity are low, probably reflecting some epidemiological constraints limiting their genetic divergence, a possible recent emergence or insufficient sampling to date.

PPV-An (from “ancestral”). A putative PPV strain represented by a recently identified isolate from eastern Albania. The full-length genomic sequence of this isolate fulfils the features of an ancestral PPV-M isolate previously hypothesized in the PPV evolutionary scenario.

Full-length genomic sequences for more than 200 PPV isolates, representing each of the ten recognized strains, are available in public databases (Fig. 3(A)). Moreover, partial sequences, focusing mainly on the 3′ terminal part of genome or the P3–6K1 region, are available for a large number of isolates, making PPV one of the genetically best studied potyviruses. The comparison of complete genomic sequences revealed from 4.7% (PPV-D versus Rec) up to 28% (cherry adapted strains versus EA) nucleotide divergence between PPV strains (Fig. 3(B)).

Recombination seems to have played a significant role in the evolutionary history of PPV. The PPV-Rec strain derives from a single recombination event involving isolates belonging to the PPV-D and PPV-M strains, with a recombination breakpoint in the C-terminus of the NIb gene. In addition, an analysis of complete genomic sequences has recently demonstrated that the PPV-D and PPV-M strains themselves share an ancestrally recombined 5′ part of their genome (5′ non-coding region, P1, HC-Pro, and N-terminus of P3). Other recently identified recombination events involve the W3174 isolate of PPV-W, which shows a mosaic structure as a consequence of recombination with PPV-M and PPV-D in the P1-HC region. The genome of PPV-T

Fig. 4 Neighbor joining phylogenetic tree of the full-length genome sequences of selected potyviruses, including Plum pox virus (in bold). The scale bar indicates branch lengths in substitutions per nucleotide.

isolates shows a recombination in the HC-Pro-P3 region (with PPV-D as a minor parent). In addition, a recent analysis involving a larger set of PPV-T isolates identified other recombination breakpoints in the central part of the genomes of divergent isolates of this strain (Fig. 4).

Thus, a growing number of available full-length genomes and of bioinformatics tools has enabled to show that besides the well-established recombinant strains (PPV-Rec, PPV-T), some other strains have recombination events in their ancient or more recent evolutionary history. Moreover, although less recognisable, it seems that at least for some PPV-W isolates, an intra-strain recombination event has also been documented. On the other hand, several strain (typical PPV-W, PPV-C, PPV-CR, PPV-CV and PPV-EA) appear to represent independent evolutionary lineages not affected by recombination.

Although the complexity of PPV diversity is unlikely to have yet been fully uncovered, phylogenetic relationships based on complete genomes suggest that PPV evolved as two major branches or groups. One group involves the M, D, Rec, T, An and EA strains, that share partially or completely a common 5' genomic region as a result of an ancestral recombination. The second group is represented by the W, C, CR and CV strains. As most isolates of these latter strains were, up to now, detected in Russia and its historically linked East European countries, an influence of such geographical separation could be connected to their limited spread or absence in other countries.

Detection

The recommended detection methods include biological indexing as well as serological and molecular assays. The use of woody biological indicators (such as peach GF305 or *P. tomentosa*) for diagnostic purposes is, however, restricted due to the labor intensive nature of such assays as well as to their length. Moreover, particular PPV strains do not seem to produce symptoms on these indicators with equal effectiveness (as in the case of GF305 and PPV-Rec).

Specific monoclonal antibodies (MAbs) against several PPV serotypes (D, M/Rec, EA, W, C) have been prepared, although some isolates may show abnormal typing properties, escaping also to the recognition by broad-spectrum antibodies. A panel of molecular methods based on RT-PCR, real-time PCR or loop-mediated isothermal amplification can be used for the accurate identification or characterization of PPV strains. Some of these methods are part of the International Plant Protection Convention-Food and Agriculture Organization (IPPC-FAO) protocol for PPV diagnosis.

Proper identification of recombinant isolates requires the use of several techniques targeting different parts of the viral genome or the use of specific primers with binding sites located on both sides of the targeted recombination breakpoint. In addition, whole genome sequencing, or sequencing of several strain-informative genome portions can provide unambiguous PPV strain identification.

An additional level in our understanding of PPV diversity derives from the analysis of PPV-infected plants by high-throughput sequencing, enabling an unbiased identification of new sequence variants. Moreover, the analysis of mixed infections involving different PPV variants/strains and their persistence, until now not well documented, is another challenge in PPV research.

Virus Spread

Natural spread of PPV occurs through aphid vectors from neighboring infected reservoirs. The aphids can acquire the virus from leaves or young shoots of cultivated, wild, or ornamental *Prunus* trees, but also from contaminated fruits, indicating that fruit shipments could also represent a minor pathway for international virus movement.

The experimental host range of PPV is large, with over 60 reported host species (such as *Chenopodium foetidum*, *Nicotiana benthamiana* and *N. clevelandii*, *Pisum sativum*, *Ranunculus arvensis*, *Senecio vulgaris*, *Stellaria media*, etc.) in eight families. However, no epidemiologically significant contribution of weeds and annual herbaceous plants to the spread of PPV has been reported.

The most efficient long-range movement of the virus is linked to international exchange of contaminated *Prunus* propagation materials (rootstocks, budwood, nursery plants).

PPV is thus usually introduced in a new location by infected propagation material. Once established in the plantation, the virus is rapidly spread by aphid vectors when making test probes and migrating between plants. PPV is naturally transmitted by over 20 different aphid species (*Myzus persicae*, *M. varians*, *Aphis gossypii*, *A. craccivora*, *A. hederae*, *A. spiraeicola*, *Brachycaudus cardui*, *B. helichrysi*, *B. persicae*, *Phorodon humuli*, *Rhopalosiphum padi*, etc.).

The virus is transmitted in a non-persistent manner so that aphids may acquire it very rapidly when probing infected plants with their stylets (piercing-sucking mouthparts). However, aphids can only transmit the virus for a short time after virus acquisition as it is retained in a viable state in the aphid's mouthparts for a period of only a few minutes to a few hours. The virus appears to be lost by the aphids the first time they probe on the next plant and aphids do not remain infectious after molting nor do they pass PPV onto their progeny.

The efficiency of transmission depends on the particular aphid species, on the virus isolate and on the host species from which the virus is acquired and to which it is transmitted. As for other potyviruses, two viral proteins are known to be involved in the transmission mechanism, the HC-Pro (helper component) and the CP. The DAG and PTK amino acid motifs are highly conserved in the N-terminus of the CP and HC protein of aphid-transmissible PPV isolates, respectively, and loss of transmissibility is correlated with their deletion or modification.

Although the virus was detected in fruits and seed coat and some conflicting results have been reported in the past concerning seed transmission of PPV in some *Prunus* species, recent studies have failed to demonstrate seed transmission of PPV in any of its woody hosts.

Ecology and Control

In the countries and regions where the virus is not yet present (e.g., Australia), strict quarantine measures need to be established to prevent the introduction of PPV through legal or illegal importation of infected fruit tree propagation material or fruits. In regions where the disease is present but still localized and under control, a mix of prophylactic approaches is usually implemented, including the application of programmes for production and use of virus-free propagation material (rootstocks, budwoods), tight aphid vector control in nurseries (e.g., by application of mineral oil), regular inspection of orchards, and prompt eradication of infected plants.

In regions of endemic PPV occurrence, where eradication brings no solution to the spread of the disease, the practical measures to pursue stone fruit production rely on the use of less susceptible or tolerant genotypes. This practice, however, does not restrict the virus spread and, paradoxically, contributed in the past to the destruction of traditional high-quality genotypes in the central and south-eastern European countries (e.g., Pozegaca or Bistrita plums).

Early attempts to use cross-protection with attenuated virus isolates, a technique successfully used to control some other potyviruses (Zucchini yellow mosaic virus, Papaya ringspot virus), have not met with success in the case of PPV.

In theory, a long term PPV control could be achieved using PPV-resistant varieties. Therefore, many breeding programmes aiming at the development of such varieties have been engaged. They were based on the use of natural resistance sources identified mainly within the *P. armeniaca*, *P. davidiana* and *P. domestica* germplasms. Efficient breeding progress is, however, complicated by the high degree of heterozygosis, the existence of incompatibility barriers between species, the long generation times and the length and non-standardisation of the resistance tests. Some progress has been achieved in plum and apricot, with the deployment of a few resistant varieties in some countries. However, the durability of these resistances remains an open question and so is their stability if confronted to the high diversity of PPV strains.

Development of genotypes with a hypersensitive response as an active defense mechanism against PPV is another promising way to produce resistant fruit trees or rootstocks, as was demonstrated for some plum varieties (e.g., Jojo), but no hypersensitivity sources are so far known in apricot and peach.

The pathogen-derived resistance strategy and the use of sequence-specific gene silencing offer a complementary approach for the development of PPV-resistant stone fruit cultivars. Experimental herbaceous hosts or *Prunus* plants transformed with different regions of the PPV genome (i.e., P1, HCPro, CI, NIa, NIb, or CP) or with post-transcriptional gene silencing (PTGS)-inducing hairpin-constructs containing viral transgenes have been developed and shown to provide partial or complete resistance to PPV. The transgenic plum "HoneySweet", transformed with a sense PPV CP gene construct, has been shown to be highly resistant to PPV infection and was recently approved for commercial cultivation in the USA, although its use is so far local and limited.

The most recently explored strategies rely on interactomics or genetic studies aimed at the identification and inactivation of host susceptibility factors, such as the translation initiation factor eIF4E and its isoforms.

Glossary

Aphid-borne Is a term used to describe aphid-transmitted viruses that infect plants.

Argonaute Are the catalytic component of RNA-induced silencing complexes. They associate with cellular or virus-derived small interfering RNAs. Together, this complex targets cellular or viral RNA for degradation or translational repression, resulting in gene silencing.

F-box Is a conserved region of P0 that mediates interaction with Argonaute protein 1, leading to Argonaute protein 1 ubiquitination and degradation.

Gene silencing Also known as RNA interference, is a sequence-specific gene inactivation system mediated by small interfering RNAs (siRNAs). It downregulates RNA accumulation without affecting DNA sequence.

Leaky scanning Happens during initiation of translation when a start codon is skipped over in preference for another start codon located downstream on the mRNA. This process allows translation of several proteins from the same mRNA.

P0 Is the silencing suppressor encoded for by poleroviruses.

Phloem-limited Refers to viruses that can only replicate in the phloem of the host plant. These viruses cannot infect mesophyll cells and are generally not transmitted mechanically.

Poleroviruses Are viruses in the genus *Polerovirus* within the family *Luteoviridae*. They are obligatorily transmitted by aphids, phloem-limited, and encode a strong silencing suppressor (P0).

Ribosomal frameshift Occurs during translation of an mRNA with two overlapping open reading frames. During the shift, the ribosome slips one base backward towards the 5'-end or one base forward towards the 3'-end. The result is the fusion of two proteins encoded for by different open reading frames on the same mRNA.

Ribosomal read-through Occurs when ribosomes overlook a stop codon and continue translation.

Silencing suppressors Are proteins encoded by viruses, which interfere with gene silencing. They prevent degradation of viral RNA, enhance transcription of viral RNA, and alter silencing of cellular genes. Combined, these effects are in part responsible for symptom development in virus-infected plants.

Introduction

The family *Luteoviridae* consists exclusively of plant infecting viruses divided into three genera: *Luteovirus*, *Polerovirus*, and *Enamovirus* (Table 1). *Luteoviruses* diversified into three genera approximately 1500 years ago in correlation with the expansion of agriculture. Members of the genus *Luteovirus* (luteoviruses) contain the standard genome of the entire *Luteoviridae* family: a single, positive single-stranded RNA (ssRNA) encoding the seven proteins P1 through P7 with multiple overlapping open reading frames (ORFs).

Barley yellow dwarf virus (BYDV) is the type species of the genus *Luteovirus*, which encode a weak silencing suppressor (P4). Members of the genus *Polerovirus* (poleroviruses) are similar to luteoviruses and contain an additional protein (P0) that is a strong silencing suppressor. Luteoviruses and poleroviruses shared a common ancestor approximately 900 years ago with P0 deriving separately in the polerovirus lineage. The type species of the genus *Polerovirus* is *Potato leafroll virus* (PLRV). *Pea enation mosaic virus* (PEMV) is the type species of the genus *Enamovirus* (enamoviruses), which encode P0 but not P4. Within the family *Luteoviridae*, BYDV and PLRV infect important staple crops and cause major economic damage. However, poleroviruses are the most damaging and diverse genus, and have a wide host range.

Poleroviruses have a single, positive ssRNA genome of 5.3–5.7 kb, encapsidated in an icosahedral non-enveloped virion (Fig. 1). Unique features of poleroviruses include obligate transmission by aphids in a circulative, non-propagative manner, infection restricted to the phloem, and lack of mechanical transmission. Symptoms induced by poleroviruses include stunting,

yellowing, a streaking pattern, and stiff leaves. These symptoms are often confused with adverse environmental factors. Most poleroviruses can be present in seed, tubers, and plant parts used for vegetative propagation. Furthermore, some plant-virus combinations remain asymptomatic. Currently, there are 32 species in the genus *Polerovirus* infecting both monocots and dicots (Table 1). These include economically important staple crops including maize, wheat, sugarcane, and potato. Poleroviruses with the most economic importance are PLRV, Sugarcane yellow leaf virus, and three beet-infecting poleroviruses.

Polerovirus Physical Properties

The polerovirus virion has a T3 icosohedral symmetry with an average diameter of 23 nm (Fig. 1). The capsid is formed by 180 monomers that consist mainly of the coat protein (CP) (approximately 23 kDa) and also contain minor amounts of a readthrough protein (approximately 80 kDa). The readthrough protein substitutes one coat protein monomer when assembling the virion. The ratio of CP to readthrough protein varies from 4:1 to 100:1. The thermal inactivation point is between 50°C and 65°C, with a dilution endpoint between 10⁻³ and 10⁻⁴. Polerovirus virions withstand deep-freeze and thaw, and withstand chloroform and detergents. The longevity in sap at 2°C is between 5 and 10 days.

Polerovirus Genome Organization and Gene Expression

The polerovirus genome consists of a single, positive-strand ssRNA encoding P0 through P7 organized in overlapping ORFs (**Fig. 2(A)**). The 5'-end is protected by the genome-linked protein VPg. The 3'-end contains an -OH group and lacks a poly-A tail. Two sub-genomic RNAs are formed during replication. Translation of polerovirus proteins involves a combination of strategies: leaky scanning, internal ribosomal entry, frameshift, and ribosomal read-through (**Fig. 2(B)**). Additionally, VPg is released from protein P1 by protease processing.

Proteins P0 and P1 are translated from the genomic RNA using leaky scanning and alternate translation initiation codons (**Fig. 2(B)**). P1 can be expressed either individually or fused with P2. When P1 is expressed by itself, it contains two putative domains: VPg and a protease that releases VPg. A ribosomal frameshift produces a P1–P2 fusion protein that generates the RNA-dependent RNA polymerase (RdRp) responsible for viral RNA replication and sub-genomic RNA synthesis. P2 is never expressed by itself. Replication associated protein 1 (Rap1) is translated from genomic RNA through an internal ribosome entry site (IRES).

Protein 3a and the movement protein (MP, P4) are translated by leaky scanning from sub-genomic RNA1 and both are involved in virus movement along with the CP. A ribosomal read-through is required for the translation of the CP read-through (P3–P5), which is less abundant than the CP (P3). An amber stop codon (UAG) separates these ORFs in sub-genomic RNA1 (**Fig. 2(B)**). The CP read-through is not necessary for virion formation, but it is essential for aphid transmission and virus movement in plants. The N-terminal half of the CP read-through determines vector specificity by regulating the efficiency of virus movement through the salivary tissues and gut. Accordingly, mutants lacking the CP read-through accumulate to low levels and are not transmitted by vectors. The C terminal half of the CP read-through is involved in efficient virus movement, tissue tropism, and symptom development in plants.

Several proteins in the genome are currently not well understood. P3a is newly discovered part of the genome. It sits directly upstream of the CP ORF (P3) and is translated by a non-AUG start codon. P3a is required for long-distance movement of poleroviruses. Proteins P6 and P7 are translated by leaky scanning from sub-genomic RNA2. P7 has nucleic acid binding properties. However, the biological role of P6 and P7 remains to be determined.

Polerovirus Phylogenetic Diversity

The evolutionary relationship and phylogenetic diversity of poleroviruses is just beginning to be elucidated. Published studies used the CP and read-through domains based on the assumption that they are highly conserved (**Fig. 3**). Based on the CP

Fig. 2 Schematic representation of polerovirus genome organization and gene expression. Single lines represent non-coding regions and labeled boxes represent cistrons. Sub-genomic RNAs, their formation and proteins translated from them are indicated. (A) Generalized polerovirus genome organization. Coordinates are based on Potato leafroll virus accession number KY856831. (B) Polerovirus gene expression strategies include formation of sub-genomic RNAs, translation by IRES-mediated internal initiation, leaky scanning, ribosomal frameshift, and ribosomal read-through. Protein 1 is processed into mature VPg by proteolysis. Pro: Putative protease. VPg: Viral protein genome-linked. RdRp: RNA-dependent RNA polymerase. Rap1: Replication associated protein. CP: Capsid protein, major and minor. MP: Putative movement protein. p3a: Protein essential for systemic virus movement. IRES: Internal ribosomal entry site.

(Fig. 3(A)), PLRV is an out-group, while Pepper yellow leaf curl virus (PYLCV), Pepper vein yellows virus (PeVYV), and Pepper yellows virus (PepYV) clustered on the same branch, and probably evolved from TVDV. However, the N-terminus of the CP read-through (Fig. 3(B)) separates Tobacco vein-distorting virus (TVDV) and places Cucurbit aphid-borne yellows virus (CABYV) close to pepper-infecting poleroviruses. In contrast, the C-terminus of the CP read-through (Fig. 3(C)) separates pepper-infecting poleroviruses and place TVDV close to PYLCV. Differences in the arrangements of poleroviruses based on CP, N, or C terminal parts of the CP read-through suggest that RNA recombination occurs frequently and is an important contributor to the evolution of poleroviruses.

Polerovirus Transmission

Polerovirus species have evolved to be efficiently transmitted by particular aphid species. PLRV is efficiently transmitted by *Myzus persicae*, while maize poleroviruses are efficiently transmitted by the corn leaf aphid (*Rhopalosiphum maidis*). Other aphids that vector poleroviruses include *R. padi*, *Stiabion avenae*, and *Aphis gossypii*. Aphids vector poleroviruses in a circulative, non-propagative manner.

The cycle begins when an aphid feeds on a polerovirus-infected plant. The virus first will reach the salivary glands of the aphid. It has been found that the read-through domain is not required for the virion to cross the salivary gland, but it does improve the success of the transport. If the species is from a yellow dwarf lineage, the virion then moves through the hindgut. If the species

Adapted with permission from Dombrovsky, A., Glanz, E., Lachman, O., *et al.*, 2013. The complete genomics of Pepper yellow leaf curl virus (PYLCV) and its implications for our understanding of evolution dynamics in the genus Polerovirus. PLoS One 8, e70722. doi:10.1371/journal.pone.0070722.

mainly uses dicots as their host, such as PLRV or Beet western yellows virus (BWYV), the virion instead moves through the midgut. Once inside the gut, the virus normally moves between the cytoplasm and the epithelial cells. It then fuses with the plasmalemma and is released between the basal lamina and the membrane. Aphids can then release the virion into the phloem parenchyma and/or the companion cells to initiate local infection. Cell-to-cell and systemic infection may occur and require the combined activity of the movement protein, capsid protein, capsid protein read-through, and P0. Phloem-limited viruses cannot normally be mechanically transmitted. However, using particle bombardment, infection has been achieved with PLRV and BWYV. The high number of aphid vectors allows poleroviruses to infect a wide range of hosts.

Potatoes, sugarcane, and beets are important species infected by poleroviruses. These all propagate in a vegetative manner. Poleroviruses can spread through infected contaminated plants parts used for propagation, such as tubers and sugarcane cuttings.

Virus-Virus Interactions

Co-infections of PLRV with Potato virus X (PVX) (*Potexvirus*) or Potato virus Y (PVY) (*Potyvirus*) result in an enhancement in symptom severity and yield loss. Similarly, co-infection of Brassica yellows virus (BrYV) (unassigned *Polerovirus*) and Pea enation mosaic virus 2 (PEMV-2) (*Umbravirus*) results in similar synergism. PEMV 2 is an umbravirus that accompanies PEMV as a satellite virus. PEMV-2 can only infect plants when a member of the *Luteoviridae* is present. Co-infection of BrYV and PEMV-2 results in higher accumulation of BrYV, more severe symptoms, and the acquisition of mechanical transmission.

Co-infection of BWYV and the potyvirus Beet mosaic virus (BtMV) causes faster systemic virus movement and earlier, more severe symptoms. The combination of the polerovirus and the potyvirus disrupts photosynthesis and vascular transport, and both

viruses accumulate to high levels when co-infected. Experimentally, the potyvirus helper-component proteinase (HC-Pro), a strong silencing suppressor, increased the accumulation of PLRV. It also allowed the virus to spread into *mesophyll* cells.

Maize lethal necrosis is a re-emerging disease of current epidemic proportions in Sub-Saharan Africa. Maize lethal necrosis disease was discovered in 1976 in Nebraska and Kansas, USA. It was caused by Maize chlorotic mottle virus (MCMV) in combination with a potyvirus, Sugarcane mosaic virus (SCMV). Several recent studies have found poleroviruses in maize in combination with MCMV, SCMV, or both. The poleroviruses detected include the Maize yellow dwarf virus-RMV (MYDV-RMV), Maize yellow mosaic virus (MaYMV), and Barley virus G (BVG). However, MYDV-RMV was the most common. Plants with a combination of a polerovirus, SCMV, and MCMV have atypical symptoms. These and other observations suggest that poleroviruses, in combination with MCMV, could also cause maize lethal necrosis disease.

Silencing Suppression by Poleroviruses

In plants, gene silencing is an essential component of antiviral defense. Virus infection induces antiviral gene silencing. Argonaute (AGO) proteins are the catalytic components of the RNA-induced silencing complex (RISC) and associate with cellular or virus-derived small interfering RNAs (siRNA). Binary complexes formed between argonaute proteins and siRNAs specifically target RNA, including viral RNA, complementary to the siRNA. They have also been implicated in cell-to-cell and systemic movement of gene silencing signals. This results in amplification of gene silencing in areas beyond the initial activation site, thereby conferring virus immunity.

In order to establish infection and move within plants, viruses encode specialized proteins that suppress gene silencing. In poleroviruses, P0 is a silencing suppressor. P0 silencing suppression activity has been demonstrated for 10 of the 32 poleroviruses (Table 1). For Beet chlorosis virus (BChV), and some strains of Beet mild yellowing virus (BMV), no silencing suppression activity was found for P0. For all other poleroviruses, no information is available or the suppression activity of P0 has not been determined. In standard experimental assays, for some poleroviruses, P0 suppresses either local or both local and systemic gene silencing.

P0 suppresses gene silencing by targeting argonaute 1 (AGO1) protein for degradation by ubiquitination. Through the F-box-like motif, P0 interacts with the DUF1785 motif in AGO1 to mark it for degradation. In *Arabidopsis thaliana*, the P0 F-box-like motif interacts with the F-box of the S phase kinase-associated protein 1 (SKP1) and with the ASK1 and ASK2 orthologues. AGO1 is the primary interaction partner of microRNAs and is a crucial for normal plant development. Thus, symptoms induced by polerovirus infection are in part due to the effect on AGO1, and potentially other AGO proteins being tagged for degraded by P0 which in turn affects normal plant development.

Potato Leafroll Virus

PLRV is the first polerovirus discovered, one of the most damaging poleroviruses worldwide, and the most damaging potato virus. It is highly prevalent and has been found on every continent except Antarctica. PLRV was first detected in the 1770s, causes 50%–60% yield loss, and costs the United States 100 million-dollars yearly. PLRV is transmitted by infected tubers and by aphids. When the virus is transmitted by aphids, symptoms begin in young, top leaves that roll and turn pale. When grown from an infected tuber, the plants may be pale or dwarfed, and the leaves may be upright, rolled, yellow, or brittle (Fig. 4(A)). However, the appearance of water-soaked leaves is usually the first symptom. In the stem and the tuber sieve tubes, abnormal amounts of callose accumulates. The carbohydrates in the leaves reach high levels causing the phloem transport to be impaired, which results in tuber reduction. This could occur because photo-assimilation is reduced, sucrose is unable to enter the phloem, or a combination of the two. These factors result in leaves with an upright and rolled appearance. In some cultivars, the margins of the leaves may turn purple or red and develop necrosis in later stages. This necrosis starts in the phloem of the petioles and stems.

Sugarcane Yellow Leaf Virus

Worldwide, damage by poleroviruses in sugarcane is a close second to PLRV. ScYLV is a good representation of the yellow leaf or yellow dwarf viruses amongst poleroviruses. ScYLV was first discovered in Hawaii in 1989 and is distributed world-wide. Currently, it is primarily detected in South America, Asia, and the Pacific islands. ScYLV affects sugarcane production in over 90 countries, which grow sugarcane for sugar, biofuel, and fibers. Crops affected by ScYLV have losses that reach up to 43%, and it is spread by infected seed canes and aphids. ScYLV infection reduces the cane thickness, the number of canes produced, and the rate of photosynthesis in the plant. It causes yellowing at the midrib (Fig. 4(B)), and, at 6–8 months, the yellowing spreads laterally to the leaf lamina and causes necrosis at the tip. Because of the short internode spacing, this causes the plant to be dwarfed. Interestingly, when co-infected with a certain bacterium, *Leifsonia xyli* sub species *xyli*, it increases the severity of the disease. Even when the virus is latent in the plant, the yield is decreased, especially in non-resistant varieties. Unfortunately, all yellow leaf viruses are hard to distinguish from normal environmental damage.

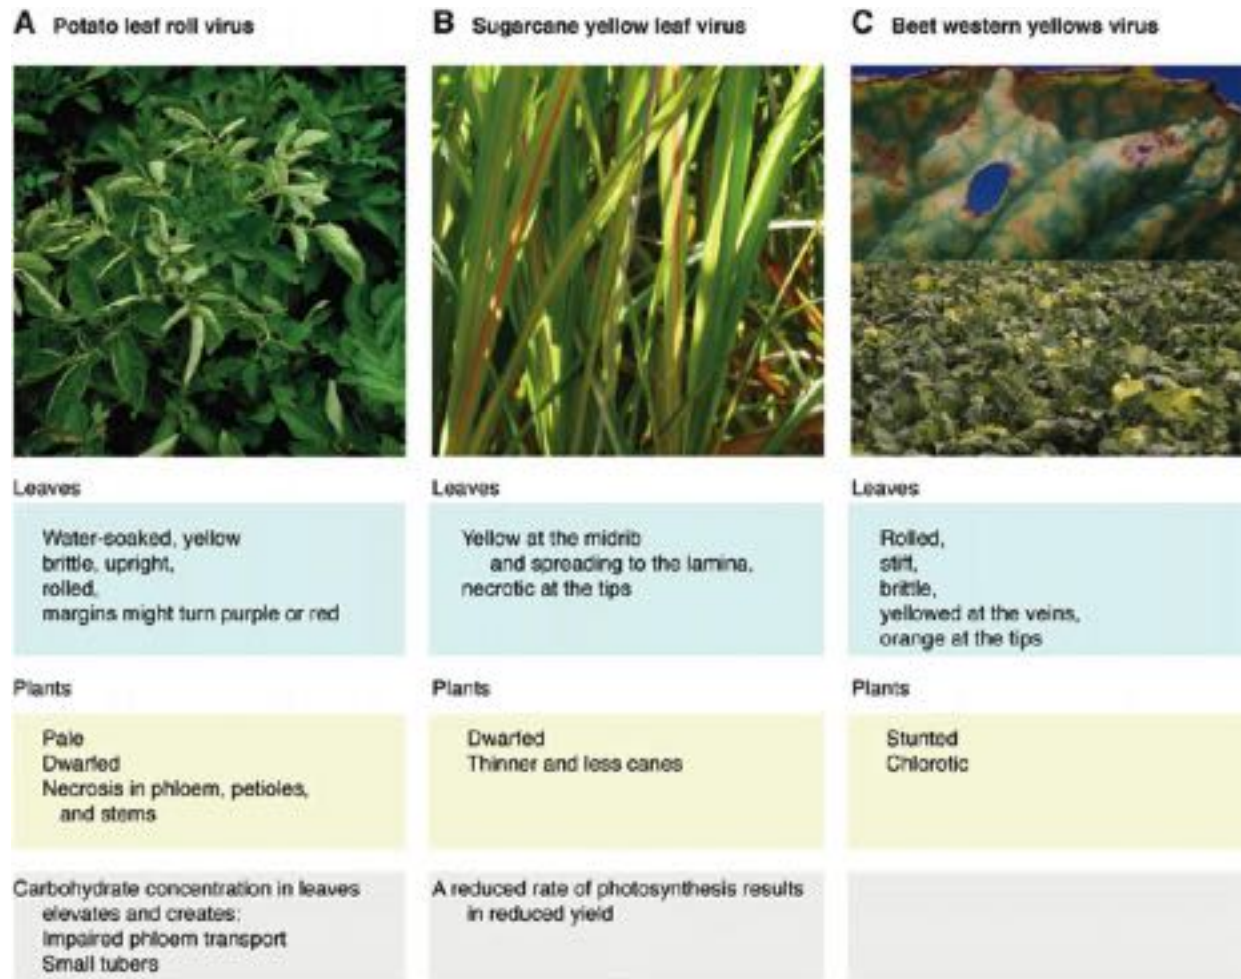

Fig. 4 Representative symptoms, in leaves and whole plants, caused by the top three poleroviruses. Other features of the symptoms are described below the images. (A) Symptoms caused by Potato leafroll virus in potato plants and leaves. (B) Symptoms caused by Sugarcane yellow leaf virus in sugarcane. Beet Poleroviruses

The three main poleroviruses infecting beet are BWYV, BMV, and BChV (**Table 1**). Most of the strains are different isolates of BWYV originating from Europe. Within the last decade, the virus has spread to Australia and resulted in a 26% yield loss in pluses, canola, and various vegetables. In canola, 59% of the 65% yield loss was due to BWYV alone. BMV is also known to result in about 22% crop loss if it appears in June. However, it has been found that these viruses have a much broader host range within the whole *Amaranthaceae* family, temperate legume crops, and brassicas. They also widely infect the weeds that grow around these crops. Of the beet-infecting poleroviruses, BChV has a smaller host range because it only infects sugar beets. These persistent viruses are transmitted by a wide variety of aphids, with the highest being the genus *Myzus*. Normally, sugar beets are durable crops that are tolerant to drought and can withstand intense wilting with no yield loss. However, poleroviruses cause stunting, chlorosis, rolling leaves, stiff followed by brittle leaves, and yellowing in the veins (**Fig. 4(C)**). Some leaves may turn orange rather than the typical yellow, which starts at the tip of the leaves. Beet-infecting poleroviruses remain problematic because of their impacts on crops, wide host range, and difficulty to diagnosis.

Diagnosis

There are several methods of detecting poleroviruses. The first test designed was the Ingel–Lange test. This test stained callose with a resorcin blue dye in the tubers of a potato infected with PLRV. Currently, poleroviruses are detected using a variety of RNA-based

and protein-based approaches. Protein-based approaches use antibodies that recognize the capsid protein. The most common protein-based approach is enzyme-linked immunosorbent assay (ELISA). A variation is the double antibody sandwich ELISA. Other protein-based approaches include immune-electron microscopy, immune-electrophoresis, and double diffusion agar tests.

RNA-based approaches include reverse-transcription polymerase chain reaction (RT-PCR), deep sequencing of the siRNAs, and high-throughput sequencing of transcript RNA. There are universal polerovirus primers for detection by RT-PCR. Universal primers Pol-G-F and Pol-G-R amplify a 1.4 kb PCR product spanning part of the RdRp gene, the intergenic region, and the complete CP gene. Additionally, northern blotting may be used to detect genomic and sub-genomic RNAs.

Electron microscopy is commonly used to visually detect poleroviruses. Using the transmission electron microscope, Cereal yellow dwarf virus (CYDV), BWYV, PLRV, and CABYV have been observed being transported through the gut and epithelial cells into the aphid. Electron microscopy was also used to track the readthrough domain to determine its role inside the aphid.

Disease Management

Polverovirus resistant plants are not common. In crops of economic importance, there are no polerovirus-resistant varieties. Varieties that do exist are only resistant to one or a few strains of the virus. Because resistant cultivars impose selection pressure and viruses mutate quickly, viruses break genetic resistance within a few years.

Since poleroviruses are vectored by aphids, physical barriers have been implemented to prevent polerovirus spread. Plastic reflective mulch can be placed around the crops. UV wavelengths will be reflected, thus repelling the aphids. Floating row covers with a fine mesh can also physically block the aphids from reaching the plant. Topical approaches include mineral oil and aphicides. Mineral oil can be applied to crops to smother aphids. Aphicides can be used on plants similar to chemical pesticides.

Carefully planned planting can reduce virus transmission by aphids. Planting when aphids are low, like after a short rain season, could potentially reduce the number of aphids in the field. This strategy can then be combined with timed pesticide use. Government restricted closed seasons for planting certain crops will also reduce polerovirus transmission. Several countries already restrict crop planting during certain times, but the approach could be further expanded around the globe. Farmers should also practice good crop rotation and diversification. A maize and soybean rotation will likely have different aphid vectors, so there is a decreased likelihood of continual crop infection. A less practiced method is to control the weeds in the field. Weeds that are not removed between crop planting could still be infected, thus leading to crop infection in the next season. It is also good practice to burn any infected plant material because it is the only surefire method to destroy the virus. This method also eliminates the possibility aphids may feed on infected plant material and spread the infection to healthy plants. Aphids are attracted to bare soil, so farmers should work to plant crops closer, include cover crops, and have untilled soil. Preventative measures provide options to limit poleroviruses exposure, but the possibility of resistant plants remains the only option to fight infection directly.

Spore balls Resting spores (cystosori) of *Spongospora subterranea* found in lesions or pustules (powdery scabs) on potato tubers; a single cystosorus comprises 500–1000

resting spores aggregated to form in a ball that is partially hollow, traversed by irregular channels.

Spraing Virus disease symptoms of internal brown lines and arcs in potato tuber flesh.

Introduction

Pomovirus is a genus of plant viruses assigned to the family *Virgaviridae*. Pomoviruses have tubular rod-shaped particles and tripartite genomes; they are transmitted by soil-borne zoosporic organisms belonging to two genera (*Polymyxa* and *Spongospora*) in the family *Plasmodiophoraceae*. Pomoviruses have limited host ranges, infecting species in a few families of dicotyledonous plants. Agriculturally important hosts include potato and sugar beet. There are six member species in the genus *Pomovirus*: *Potato mop-top virus* (PMTV), *Beet soil-borne virus* (BSBV), *Beet virus Q* (BVQ), *Broad bean necrosis virus* (BBNV), *Colombian potato soil-borne virus* (CPSbV) and a tentative member *Soil-borne virus 2* (SbV2). BVQ and BSBV can occur in mixed infections with the benyvirus *Beet necrotic yellow vein virus* (BNYVV).

Taxonomy and Classification

The classification of tubular rod-shaped viruses transmitted by soil-borne plasmodiophorid vectors was revised in 1998 to establish four genera: *Furovirus*, *Pomovirus*, *Benyvirus*, and *Pecluvirus*. The revision was prompted by new virus sequence information that revealed major differences in genome properties (number of RNA segments, sequence, and genome organization). The genus *Pomovirus* is assigned to the family *Virgaviridae*. *Pomovirus* is a siglum from *Potato mop-top virus*, the type species.

Physical Properties of Particles

Pomovirus particles are hollow, helical rods, 18–20 nm in diameter, comprising multiple copies of a single major coat protein (CP; *c.* 19–20 kDa). The CP gene is terminated by a UAG (or UAA in BBNV) stop codon that is thought to be suppressible, readthrough of which would produce a fusion protein with a read-through domain (RTD) of variable mass (54–104 kDa), CP-RTD. One or a few copies of the CP-RTD fusion protein are present at the extremity of PMTV particles and thought to contain the 5' end of the virus RNA. *Pomovirus* particles are fragile and particle size distribution measurements are variable; PMTV

Fig. 1 Diagram of the PMTV genome organization; boxes indicate ORFs with the molecular masses of predicted protein products (kDa) indicated within.

particles have predominant lengths of 125, 137, and 283 nm. PMTV particles sediment as three components with sedimentation coefficients ($S_{20,W}$) of 126, 171, and 236S.

Genome Properties and Functions of the Encoded Proteins

Complete genome sequences are available for four member species. An almost complete sequence (without the 5' and 3' untranslated regions (UTRs)) is available for BBNV. Complete sequences of two genomic components, namely, RNA-rep and RNA-TGB are available for SbV2. Pomovirus genomes comprise three species of positive-sense single-stranded RNA (ssRNA) of c. 5.8–6.2, 2.8–3.4, and 2.3–3.1 kb (Fig. 1). RNA-rep encodes the replicase proteins. It contains a large open reading frame (ORF) that is interrupted by a UGA stop codon (ORF1) (or UAA in BVQ and BSBV; UAG in SbV2); the sequence continues in-phase to encode a readthrough protein (204–207 kDa). The protein encoded by ORF1 (145–149 kDa) contains methyl-transferase and helicase motifs while the RTD contains the GDD RNA-dependent RNA polymerase (RdRp) motif. Phylogenetic analysis reveals that the RdRps of the pomoviruses and the furovirus Soil-borne wheat mosaic virus share between 50% and 60% sequence identity. Phylogenetic analysis of available PMTV RNA-rep sequences reveals two major clades. The isolates from Peru, Colombia, Europe, China, Canada and USA group together in clade I, whereas clade II is exclusively represented by Colombian isolates.

The 5' UTR of pomovirus RNAs contains the starting sequence GU(A)_{1–4}(U)_n (except BVQ RNA-rep which begins with AUA, CPSbV RNA-rep and RNA-CP which begin with ACAT(G)_{4–5}TATT, and CPSbV RNA-TGB as well as RNA-rep and RNA-TGB of SbV2 have a different sequence at the 5' end). The RNAs are probably capped at the 5' end since the RNA-rep-encoded viral replicase contains methyl-transferase motifs associated with capping activity. The terminal 80 nt of the 3' UTR can be folded into a tRNA-like structure that contains an anticodon for valine. Both BSBV and PMTV RNAs were shown to be valylated experimentally. Different from other five pomoviruses, a tRNA-like structure of CPSbV genomic components contains an anticodone for leucine.

The virus movement proteins (MPs) are encoded on RNA-TGB of pomoviruses. Three 5'-proximal overlapping ORFs encode a conserved module of movement proteins known as the triple gene block (TGB). TGB movement proteins are found in the genomes of other rod-shaped viruses in the families *Virgaviridae* (hordei-, gora- and pecluviruses) and *Benyviridae* (benyvirus) and in some genera of monopartite filamentous viruses in the families *Alphaflexiviridae* and *Betaflexiviridae*. The TGB proteins (TGB1, TGB2, and TGB3) are named according to the position of their genes on the RNA and have molecular masses of 48–54, 13, and 20–22 kDa, respectively. The TGB1 contains three structurally distinct domains: an unstructured intrinsically disordered N-terminal domain (NTD), an ordered internal domain (ID) and a helicase domain (belonging to the viral superfamily 1 RNA helicases). TGB1 NTDs of different pomoviruses do not share obvious sequence similarity. TGB1 binds RNA and is thought to interact with genomic RNAs to facilitate movement. The NTD contains two nucleolar localization signals, interacts with nuclear transport receptors of Importin- α family and accumulates in the nucleoplasm and in the nucleolus. The nucleolar passage of PMTV TGB1 is needed for the virus systemic movement. The half of ID of PMTV TGB1 is predicted to form an α -helix that seems to mediate oligomerisation of TGB1 through self-interaction. The ability for self-interaction (TGB1 oligomerisation) is crucial for the cell-to-cell movement of PMTV. PMTV TGB1 also interacts (through its helicase domain) with a read-through domain (RTD) of CP-RTD at one extremity of the virions assisting in the systemic movement of the virus particles.

The sequence of the second TGB protein is the most conserved with BSBV, BVQ, and PMTV sharing 63%–75% nt sequence identity and 49% identity with that of BBNV; there is little sequence identity among the TGB3 sequences. Analysis shows that TGB2 and TGB3 proteins contain two hydrophobic regions (predicted transmembrane domains) separated by a hydrophilic domain and these proteins are associated with intracellular membranes in infected plants. PMTV TGB2 associates with the membranes of endoplasmic reticulum (ER), mobile granules in the cytoplasm, components of endosomal network, and the outer

membrane of chloroplasts. PMTV TGB2 also binds RNA in a sequence non-specific manner, but is not required for RNA replication, although it was suggested that TGB2 might play a role in delivering the viral RNA to the chloroplast membranes for replication. PMTV TGB2 can increase permeability of plasmodesmata (so-called the size exclusion limit, SEL) and together with TGB3 (which also increases SEL of plasmodesmata) is thought to facilitate movement of the viral ribonucleoprotein (vRNP) complexes through plasmodesmata to the neighboring cells (cell-to-cell movement).

At the subcellular level, TGB3 associates with the ER, motile granules, stationary aggregates at the periphery of the cell, termed “peripheral bodies”, and plasmodesmata. Similar to TGB2, the TGB3 protein of pomoviruses contains two trans-membrane domains and embedded into the membranes in U-shaped orientation with its central hydrophilic domain protruding into the ER lumen and N-terminus located in the cytosol. TGB3 contains a conserved tyrosine-based motif YQDLN involved in targeting TGB3 to plasmodesmata.

In PMTV and BBNV, a fourth small ORF of RNA-TGB is predicted to encode an 8 kDa cysteine-rich (8K) or 6 kDa glycine-rich protein, respectively, whereas no such ORF is present in BSBV, BVQ, CPSbV or SbV2. The 8K protein is classified as a zinc-finger protein with a putative SWIM zinc-finger motif characterized by a consensus sequence CxC_xCxC, in which C stands for cysteine residues and x refers to any aa residue. The 8K protein of PMTV is not needed for the virus movement or infection of *Nicotiana benthamiana*. However, 8K is essential for the efficient virus accumulation and the appearance of the viral symptoms is delayed in the absence of the 8K expression. The 8K protein functions as a viral suppressor of RNA silencing (VSR). Mutations resulting in substitution of cysteine residues with alanines within a putative SWIM zinc-finger motif abolish 8K VSR activity. Comparison of the 8K sequences from more than 80 isolates reveals that the 8K protein sequences show an extraordinary variability with 23 variable sites per 68-aa-residues-long protein. Moreover, the 8K ORF is under positive selection, whereas other PMTV ORFs are under neutral or negative selection. The extraordinary variability and positive selection seem to drive efficient RNA silencing suppression activity of the 8K protein as the 8K protein encoded by certain PMTV isolates has stronger RNA silencing suppression activity compared those encoded by other isolates. Site-directed mutagenesis identified a serine residue (Ser-50) as being essential for enhanced VSR activity of one natural variant of 8K. Next generation sequencing (NGS) of small RNA populations in the presence of the 8K proteins with contrasting abilities to suppress RNA silencing (strong versus weak) reveals a lower abundance of 21 nt and 22 nt small interfering RNAs (siRNAs) with uracil (U) residue at the 5' end after expression of relatively strong 8K natural variant compared to that of a weak 8K allele. As accurate sorting of siRNAs into ARGONAUTE (AGO)-containing antiviral RNA-induced silencing complex (RISC) – with AGOs preferentially binding to siRNA with certain residue at the 5' terminus – is important for antiviral defense, it has been speculated that the natural variant of 8K with relatively strong RNA silencing suppression activity may destabilize either siRNAs with U residue at the 5' end or complexes into which such siRNAs are sorted, i.e., AGO1-containing RISC that play a primary role (along with AGO2) in antiviral RNA silencing. The sequence of the 8K ORF along with the beginning of the sequence of TGB1 ORF is involved in biogenesis of a defective interfering (DI) RNA. DI RNA is readily detectable, accumulates at high levels in the virus-infected plants, and interferes with efficient virus accumulation. The disruption of a predicted minus-strand stem-loop secondary structure comprising complementary sequences of the 5' TGB1 ORF and the 3' 8K ORF results in inhibition of DI RNA production suggesting intramolecular template switching during positive-strand synthesis as a possible mechanism for the DI RNA biogenesis.

Phylogenetic analysis of available PMTV RNA-TGB sequences reveals two major clades. The isolates from Peru, Colombia, Europe, China, Canada and USA group together in clade I, whereas clade II is represented by a Peruvian isolate.

The CP and CP-RTD proteins are encoded on RNA-CP. The PMTV RNA-CP is of variable size, from 2315 to 3252 nt. The longest RNA-CP (3252 nt) is found in PMTV isolate J20 from Cajamarca, Peru. Compared to other PMTV isolates, isolate J20 has additional sequences in 3'-UTR. In most PMTV isolates, RNA-CP is 3134 nt in length. Analysis shows that RTD of PMTV and BVQ contains two transmembrane domains, TM1 and TM2, suggesting that CP-RTD is a membrane protein integrated into the lipid bilayer in a U-shaped orientation. Indeed, PMTV CP-RTD localizes to cell periphery probably through association with plasma membrane. Analysis of naturally occurring and glasshouse-propagated isolates revealed that deletions of c. 500–1000 nt occur in both field and laboratory isolates and that the deletions occur predominantly in RTD, particularly in the region toward the 3' end of the RTD ORF. Deletions in this region are correlated with loss of transmission by the natural vector *Spongospora subterranea*. Hydrophobicity analysis shows that these in-frame deletions result in the loss of the transmembrane domain TM2.

The occurrence of encapsidated deleted forms of RNA-CP and RNA-TGB in natural and laboratory isolates of PMTV has been described and sequence analysis as well as mutagenesis (for RNA-TGB) suggests that these PMTV RNAs contain sites that are susceptible to recombination possibly through a template switching mechanism. Variable base composition is found in natural isolates of BSBV in the sequence at the 3' end of RNA-TGB between the stop codon of the third TGB and the terminal tRNA-like structure.

Phylogenetic analysis of available PMTV RNA-CP sequences reveals three major clades. The isolates from Peru, Colombia, Europe, China, Canada and USA group together in clade I, whereas clade II and clade III are exclusively represented by Peruvian isolates.

Virus–Host Interactions and Movement

Cytoplasmic inclusions of enlarged ER and the accumulation of distorted membranes and small virion bundles can be seen by electron microscope examination of thin sections of BSBV- and BVQ-infected leaves. In PMTV-infected potato leaves, abnormal chloroplasts with cytoplasmic invaginations were seen in thin sections as well as tubular structures in the cytoplasm associated with the ER and tonoplast, and in the vacuole.

PMTV does not require CP for movement and it is thought that TGB1 interacts with viral RNA forming a movement competent ribonucleoprotein (RNP) complex. Studies of transiently expressed PMTV TGB proteins fused to marker proteins such as green fluorescent protein (GFP) or monomeric red fluorescent protein (mRFP) in epidermal cells of *N. benthamiana* have helped to elucidate events in intracellular trafficking and indicate that PMTV interacts with the cellular membrane recycling system. PMTV TGB2 and TGB3 were shown to co-localize on the ER (Fig. 2(a)–(c)) and in small motile granules that utilize the actin–ER network to reach the cell periphery and plasmodesmata and TGB3 contains a putative tyrosine sorting signal (YQDLN), mutation of which inhibits TGB3 localization to plasmodesmata. TGB2 and TGB3 act together to transport GFP-TGB1 to the plasmodesmata for movement into neighboring cells and TGB2 and TGB3 have the capacity to gate the plasmodesmata pore. TGB2 co-localizes in endocytic vesicles with the Rab 5 ortholog Ara 7 (AtRabF2b) that marks the early endosomal compartment. Also, protein–interaction analysis revealed that recombinant TGB2 interacted with a tobacco protein belonging to the highly conserved RME-8 (receptor mediated endocytosis-8) family of J-domain chaperones, essential for endocytic trafficking.

The systemic movement of many plant viruses occurs as virions that require expression and accumulation of CP in the infected cells. Yet, a small group of viruses including PMTV can move systemically in plants in the absence of CP as an RNP complex formed by interaction of the TGB1 protein with viral RNA. Moreover, mutational analysis revealed an essential role of CP-RTD in the long-distance movement of RNA-CP because in the absence of the CP-RTD expression PMTV CP inhibits systemic movement of RNA-CP, whereas the movement of RNA-TGB and RNA-rep is not affected. CP-RTD is needed for PMTV transmission in soil by its soil-borne vector *Spongospora subterranea* and minor amounts of CP-RTD molecules are incorporated into one terminus of the virus particles forming polar virions. Mutational analysis identified a CP-RTD domain consisting of 140 aa residues near the C-terminus as required for RNA-CP long-distance transport. Moreover, this particular domain is involved in the interaction of CP-RTD with TGB1 suggesting long-distance movement of polar virions that contain CP-RTD and TGB1 at the tip. Thus, the structure of movement-competent PMTV virions appears to be quite complex and involves at least two supplementary proteins at the particle tip.

Since PMTV TGB1 plays indispensable role in the movement of both viral RNPs (vRNPs) and polar virions identification of the host proteins as well as sub-cellular domains that interact with TGB1 has been crucial to understanding the mechanism of PMTV movement in plants. At early stages of virus infection (at the very front of infection foci) PMTV TGB1 is localized to plasmodesmata consistent with the central role of the protein in the virus movement. In addition to localization in plasmodesmata TGB1 is observed in the nucleoplasm, nucleolus and in association with microtubules (Fig. 2(d)) at later stages of virus infection (two-four cell behind the infection front). The nuclear/nucleolar localization of PMTV TGB1 is mediated by interaction of the protein N-terminus with a nuclear transport receptor Importin- α . Disruption of TGB1 nucleolar localization (through mutagenesis) or knock down of Importin- α expression or disruption of microtubules by chemical inhibitors does not affect the virus cell-to-cell movement but inhibits its systemic spread.

As the N terminus of TGB1 appears to be important for the virus systemic movement and such movement correlates with the association of TGB1 with the nucleolus and microtubules, *Nicotiana benthamiana* cDNA library was panned using a yeast two-hybrid screen to identify host proteins that interact with the TGB1 protein. The screen yielded HIPP26, a metallochaperone, as TGB1 interacting partner. The HIPP26 gene belongs to the large gene family that is unique in vascular plants. The HIPP proteins act in the heavy metal homeostasis (hence the name: Heavy metal-associated Isoprenylated Plant Protein, HIPP), involved in the regulation of transcriptional response to the biotic and abiotic stress and acts in a signal transduction as a plasma membrane-to-nucleus relay during abiotic stress. HIPP26 is post-translationally modified through lipidation (S-acylation and prenylation). Knockdown of HIPP26 expression inhibits virus long-distance movement of both virions (when all three RNA genomic components are used as inoculum) and vRNPs (produced by inoculation of RNA-rep and RNA-TGB only) but does not affect cell-to-cell movement of the virus. HIPP26 is upregulated in plants subjected to drought as well as in PMTV-infected plants. Moreover, PMTV infection protects plants from drought stress. Analysis of the spatial expression pattern of HIPP26 using HIPP26 promoter-reporter fusions reveals its vascular tissue-specific expression consistent with the role of HIPP26 in systemic movement of the virus. Biochemical and mutational analyses show that HIPP26 subcellular localization at the plasmodesmata and plasma membrane is mediated by post-translational modifications through lipidation (S-acylation and prenylation), as nonlipidated HIPP26 is mostly found in the nucleus. Furthermore, HIPP26 is predominantly accumulates in the nucleus when co-expressed with TGB1. TGB1 interacts with the C-terminal ¹⁵²CVVM¹⁵⁵ (prenyl) domain of HIPP26, and the TGB1-HIPP26 complex decorates microtubules and accumulates in the nucleolus. Overall, these data support a mechanism in which interaction TGB1 with HIPP26 results in the inhibition of the HIPP26 protein lipidation or/and de-lipidation of already modified HIPP26, thus releasing membrane-associated HIPP26 from plasma membrane into the cytosol. The HIPP26/TGB1 complex, than, localizes to microtubules and subsequently directed to the nucleus and nucleolus in Importin- α -dependent manner. In the nucleus HIPP26 activates the drought stress response to facilitate virus long-distance movement.

Host Range, Geographical Distribution, Transmission by Vector and Variability

Pomoviruses have a limited host range and are transmitted in soil by zoosporic plasmodiophorid vectors that have been classified as protists (Fig. 3). Viruses that are transmitted by plasmodiophorid vectors include pomo-, peclu-, furo-, beny- and bymoviruses and they are thought to be carried within the zoospores. The vector life cycle includes production of environmentally resistant thick-walled resting spores. The viruliferous resting spores can survive in soil for decades.

Fig. 2 Confocal laser scanning microscope images of PMTV TGB2 and TGB3 (a–c) and TGB1 (d) fluorescent fusion proteins in epidermal cells of *Nicotiana benthamiana*. Monomeric red fluorescent protein (mRFP) tagged PMTV-TGB2 was transiently expressed with green fluorescent protein (GFP) tagged PMTV-TGB3, the proteins co-localized on membranes of the ER and in motile granules seen moving on the ER network. BBNV has been reported only from Japan; it causes necrosis and stunting in broad beans and peas. It is mechanically transmitted by inoculation of sap to a few species including *Vicia faba*, *Pisum sativum*, and *Chenopodium quinoa*.

BVQ and BSBV are often found associated with BNYVV; BVQ is reported only from Europe whereas BSBV is found in sugar-beet-growing areas worldwide. No symptoms have been attributed to BSBV or BVQ alone in sugar beet. BSBV is ubiquitous virus and is often

found in the soils in sugar-beet growing areas, but the virus alone does not cause any disease in sugar beet. The viruses are thought to be transmitted in soil by *Polymyxa betae*. BVQ is mechanically transmissible only to *C. quinoa* and BSBV to members of the *Chenopodiaceae*.

PMTV is reported to have originated in the center of potato domestication – the Andean region of South America – and has now found in potato-growing regions of Europe, North and South America, Asia and recently in New Zealand; virus incidence is favored by cool, wet growing conditions. It is transmitted in soil by *S. subterranea*, also a potato pathogen which causes the tuber blemish disease powdery scab. PMTV can be transmitted mechanically to members of the *Solanaceae* and *Chenopodiaceae*.

CPSbV and SbV2 has been reported only from Colombia; the viruses seem to cause symptomless infections in potato. The viruses are thought to be transmitted in soil by *S. subterranea*. CPSbV and SbV2 are mechanically transmitted by inoculation of sap to members of the *Solanaceae* and *Chenopodiaceae*.

The complete and partial genomic sequences are available for numerous PMTV isolates from around the globe. Based on the CP-RTD sequence, two major strains of PMTV are recognized and coined as S (for “severe”) and M (for “mild”). Seven signature aa residues differ between the S (RRSIGAV) and the M (KKNVREM) strains in the CP-RTD protein encoded by RNA-CP. The M strain is only reported from Peru, whereas the S strain is found worldwide including Peru. Phylogenetic analysis identified two major genotypes (clades) for RNA-rep (I and II), two major genotypes for RNA-TGB (I and II), and three genotypes for RNA-CP (I, II and III). As PMTV has a tripartite genome, a classification of PMTV isolates based on genotype constellations has been suggested. In this classification, the genotype of each genomic RNA is taken into consideration. Four genetic constellation has been found so far. Two genetic constellations – I + I + II and UN + II + III (RNA-rep + RNA-TGB + RNA-CP, “UN”, indicates unknown genotype of the RNA-rep segment, for which sequence is not available) – are exclusively found in Peru. Another genetic constellation (II + I + I) is found in Colombia, whereas the constellation I + I + I is found worldwide including Peru and Colombia. These observations suggest that this particular constellation (I + I + I) originates from the Andean region of Peru, the center of potato domestication, and was spread to the other parts of the world. In general, greatest diversity of PMTV is found in the Andean region of South America, whereas the virus has very little variability in the rest of the world.

Serological Relationships, Diagnosis, and Control

The viruses are serologically distinct. Distant relationships have been reported between BSBV and BVQ; PMTV and Soil-borne wheat mosaic virus (*Furovirus*); and PMTV, BBNV, and tobamoviruses. PMTV, BSBV, and BVQ CPs contain a conserved sequence (SALNVAHQ) that reacts in Western blots with a monoclonal antibody (SCR70) produced against PMTV, but that is not exposed on intact particles. PMTV particles contain an immunodominant epitope at the N-terminus of the CP that is exposed at the surface along the sides of the particles and can be detected by monoclonal antibody SCR69 (Fig. 4).

The viruses can be detected by serological tests (immunosorbent electron microscopy, enzyme-linked immunosorbent assay), by assays based on the reverse transcriptase-polymerase chain reaction (RT-PCR) and by quantitative real-time RT-PCR (RT-qPCR) in leaves, roots, or tubers from naturally infected plants. PMTV is known to be erratically distributed in potato leaves and tubers and can move systemically in the absence of CP in potato leaves which raises a risk of false negative diagnosis. The problem can be overcome by using RT-PCR or RT-qPCR for detection of RNA-TGB and/or RNA-rep as RNA-CP might be absent in those samples.

PMTV causes an economically important disease affecting the quality of tubers grown for the fresh and processing markets. Tubers of susceptible potato cultivars that are infected from soil during the growing season develop “spraing” symptoms that include unsightly brown lines, arcs, or marks in the flesh sometimes accompanied by slightly raised external lines and rings (Fig. 5(a)). Potato plants grown from infected tubers display V-shaped yellow markings or chevrons on the leaves (Fig. 5(b)) and may have shortened internodes (mop-top) producing cracked or malformed tubers; both tuber quality and yield can be affected. However, the virus does not infect all plants grown from infected tubers. Haulm and tuber symptoms vary markedly with cultivar, and some cultivars are symptomlessly infected. Environmental conditions also affect disease incidence and severity, and PMTV

incidence was shown to increase with annual rainfall. Soil temperatures of 12–17°C and high soil moisture at tuber initiation favor powdery scab incidence.

PMTV can be established at new sites by planting infected tubers and once established, PMTV is a persistent problem, as the resting spore balls of the vector *S. subterranea* are long-lived and resistant to drought and agrochemicals. Viruliferous spore balls are spread readily to new sites by farm vehicles, contaminated seed tubers, wind-blown surface soil; motile zoospores can be spread through contaminated irrigation or drainage water. In certain areas, potatoes have become infected by PMTV 18 years after potatoes were last grown (the longest period recorded). There is no effective practicable means to control *S. subterranea* but decreased severity of powdery scab can be achieved by application of fluazinam to soil. In addition, disinfection of tubers with chemicals such as formaldehyde decreases virus incidence, although the efficacy of this treatment depends on the level of soil infestation where the tubers are planted and a combination of tuber and soil treatments may be more effective.

The best prospect for virus disease control is development of resistant cultivars but there are no known sources of PMTV resistance in commercial potato cultivars and most of the commercially grown cultivars are also susceptible to *S. subterranea*. However, plants transformed with virus-derived transgenes (*CP* and a mutated form of *TGB2*) have exhibited resistance to PMTV with decreased virus accumulation and incidence in tubers of plants grown in infested soil.

Glossary

Hypersensitive Reaction A specific virus strain plant defense reaction mediated by *N* genes associated with an

infection limited to tissue surrounding the initially infected cells with visible local or systemic necrosis.

Introduction

Potato virus Y (PVY) was first recognized in 1931 as an aphid-transmitted member within a group of viruses associated with potato degeneration, a disorder known since the eighteenth century. PVY is the type species of the genus *Potyvirus*, one of the six genera in the family *Potyviridae*. PVY is naturally spread by vegetatively propagated material and by aphids in non-persistent and non-circulative manners. Horizontal transmission by contact between plants and vertical transmission by true seeds have also been reported. PVY has a wide host range and is highly variable with some host specificity. Genome sequences and reliable tools for detection and strain differentiation are available. Bioassays and serology have been largely developed. PVY is one of the most damaging plant pathogens causing significant losses in four main crops around the world: potato, pepper, tomato, and tobacco. In surveys of viruses with worldwide economic importance, PVY was listed in the top-ten viruses affecting field-grown vegetables. PVY was also found responsible for damages in petunias in Europe, in eggplant crops in India and poha (or Cape gooseberry; *Physalis peruviana*) in Hawaii. Efficient control strategies depending on the crop have been developed. However, none of them seems capable to contain entirely the risks of PVY epidemics linked to virus evolution or changes of epidemiological conditions.

Viral Particle, Genome and Cytopathology

PVY particles are non-enveloped, filamentous, flexuous rods, 730–740 nm long, 11–12 nm in diameter, with an axial canal 2–3 nm in diameter and helical symmetry (Fig. 1). Each virion is composed of circa 2000 units of viral coat protein (CP) of 30 kDa, encapsidating a single-stranded, linear, positive-sense RNA molecule ($3.1\text{--}3.2 \times 10^6$ Da) of approximately 10 kb long.

The PVY genome has two distal non-translated regions (NTR) at the 5'- (from 183 to 195 nt) and the 3'- (from 326 to 407 nt) ends, with a poly-A tail at the 3'-terminus and a viral protein covalently linked (VPg) at the 5'-end. The genomic RNA contains one single open reading frame (ORF), and is translated into a large polyprotein (3061–3062 aa) cleaved in *cis* or *trans* by three virus-

Fig. 1 Purified suspension of PVY. Magnification 22,000 $\times$. Photograph: D. Thomas, CNRS-Rennes 1 University, France. The bar represents 250 nm.

Fig. 2 Schematic representation of genomic organization of PVY and polyprotein processing. The viral genome-linked protein (VPg) is illustrated by a circle at the 5'-end of the genome. The poly-A tail is presented at the 3'-end. The large open reading frame encoded by the viral genome is presented with the names of corresponding proteins (P1, HC-Pro, P3, P3N-PIPO, 6K1, CI, 6K2, VPg, NIa-Pro, NIb, CP). The short PIPO ORF overlapping the P3 protein is presented. The nucleotide and amino acids are numbered according to isolate N605 (accession number X97895). NTR: non-translated region.

encoded proteases (P1, HC-Pro, NIa-Pro) into ten functional proteins: P1 (275 aa), HC-Pro (465 aa), P3 (364–365 aa), 6K1 (52 aa), CI (634 aa), 6K2 (52 aa), VPg (188 aa), NIa-Pro (244 aa), NIb (519 aa), and CP (267 aa). An eleventh protein, P3N-PIPO, is produced by slippage of the viral polymerase at a specific motif embedded in the P3-coding region called PIPO (Pretty Interesting *Potyviridae* ORF) (Fig. 2).

These 11 viral proteins are mainly multi-functional. Some of them interact with some other viral proteins and/or with some host proteins to determine plant infection or virus plant-to-plant transmission. In the process of PVY infection, viral proteins are often associated with specific subcellular compartments (chloroplasts, endoplasmic reticulum and Golgi apparatus) where they perform their functions (Fig. 3). After PVY particles are introduced into the cytoplasm of plant cells by mechanical or vector-mediated inoculation, the PVY infection cycle is initiated by uncoating of virions and release of the viral RNA genome which is then recruited by the host translation machinery (eukaryotic initiation factors, ribosomes, etc.) to synthesize the polyprotein. After its processing, the 11 viral proteins are released. Nuclear inclusion proteins (NIa, NIb) migrate to the nucleus and cylindrical inclusion (CI) proteins accumulate in the cytoplasm by forming pinwheel-shaped inclusions. Viral replication complexes associate to the membrane of host organelles (endoplasmic reticulum, Golgi apparatus and vesicles) through the 6K2 protein. During replication, the positive-sense single-stranded RNA (ssRNA) is copied into a complementary negative-sense RNA and vice versa by

Fig. 3 Schematic representation of PVY infection cycle in infected plant cell, with the location of viral proteins and their mutual interactions. Extracted from Lacomme, C., Jacquot, E., 2017. General characteristics of potato virus Y (PVY) and its impact on potato production: An overview. In: Lacomme, C., Glais, L., Bellstedt, D.U., *et al.* (Eds.), *Potato Virus Y: Biodiversity, Pathogenicity, Epidemiology and Management*. Switzerland: Springer, pp. 1–19.

the RNA-dependent RNA polymerase (RdRp) (NIB protein) and the RNA helicase (CI protein). The obtained positive-sense ssRNA are either encapsidated to produce new virions or recruited by viral proteins (CI, CP, HC-Pro, P3N-PIPO) and host proteins to form ribonucleic complexes that move from cell to cell through plasmodesmata and systemically in phloem vessels.

Host Range

The natural host range of PVY comprises plants in nine families. It includes potato (*Solanum tuberosum* ssp. *tuberosum*), several species of native potatoes in the Andes including *Solanum andigena* and numerous *Solanum* species, pepper (*Capsicum* spp.), tobacco (*Nicotiana* spp.), tomato (*Solanum lycopersicum*), eggplant (*Solanum melongena*), Cape gooseberry (*Physalis peruviana*), ornamentals (*Petunia* spp., *Dahlia* spp.), perennial plants (*Physalis virginiana*, *Physalis heterophylla*), and a number of annual plants. Many region-specific hosts were recorded such as *Cotula australis* in New Zealand or *Sorbaria tomentosa* in Himalaya.

Weeds in the family Solanaceae are often potential inoculum sources for PVY infections in tomato and pepper crops: *Solanum nigrum* and *Solanum dulcamara* in many countries; *Solanum chacoense* and *Physalis viscosa* in Southern America; *Solanum gracile*, *Solanum aculeatissimum*, *Physalis angulata*, *Physalis ciliata*, and *Physalis floridana* in Florida. *Physalis virginiana* and *Physalis heterophylla* (perennial ground cherries) are overwintering hosts in Northern America. *Solanum dulcamara* in Western Europe or *Datura* spp. in Mediterranean countries are potential inoculum sources in potato crops as well as volunteer potatoes. Infected pepper and tomato plants, and seed and volunteer potatoes were also identified as potential sources of inoculum in tobacco crops in the USA, Canada, and Italy.

PVY is easily sap-transmitted and can be transmitted by stem- and tuber-grafting. Its experimental host range comprises plants in 495 species and in 72 genera of 31 families. It includes 287 species in the family Solanaceae (among which 141 *Solanum* species and 70 *Nicotiana* species), 28 species of Amaranthaceae, 25 species of Fabaceae, 20 species of Chenopodiaceae, and 11 species of Asteraceae. A large part of these plants show only local lesions upon PVY inoculation. *Datura stramonium*, formerly reported as a host plant, was demonstrated to be totally immune to all strains tested in 1980–1990. Some PVY isolates can infect the model plant *Arabidopsis thaliana*.

Nicotiana tabacum, *Nicotiana benthamiana*, *Nicotiana occidentalis* can be used as diagnostic species susceptible to all PVY strains. *N. tabacum* plantlets are often used as source and test plants for aphid transmission experiments. *N. tabacum* is a suitable host for

Fig. 4 Winged form of *Myzus persicae*, an insect vector of PVY. Photograph: B. Chaubet, INRAE, France.

virus purification. Yields of purification including a final step of cesium chloride gradient centrifugation usually vary from 10 to 25 mg kg⁻¹ of tobacco leaves. Leaves of *N. tabacum* are the best virus-infected material to store. Antigenic properties can be retained for 1 year in freeze-dried crude extracts. Infectivity was reported to be preserved in freeze-dried material stored over calcium chloride at 4°C for 15 years. However from our own experience numerous long-term stored isolates of PVY available in international collections are no longer infectious.

Solanum demissum Y, *S. demissum* PI 230579, and the hybrid *S. demissum* A6 are local lesion hosts. The 'A6 test' on detached leaves was commonly used in the past as a diagnostic tool for differentiating PVY from Potato virus A (PVA), another potyvirus. Cultivars of *N. tabacum*, potato and pepper, *Chenopodium amaranticolor*, *P. floridana*, some accessions of *Solanum brachycarpum* and *Solanum sparsipilum* are useful for distinguishing among PVY strains and pathotypes. Potato cultivars such as Bintje or Saco can be used to separate PVY from plants co-infected with PVA or Potato virus X (PVX). The capacity of PVY isolates from the C1 group to infect pepper (*C. annuum*) was shown to require mutations in both the CI and the P3 and/or P3N-PIPO coding regions, and seem to have evolved several times independently.

Transmission

In natural conditions, different transmission routes are used by PVY. The first one is vertical transmission from infected mother plants to their progeny. Potato plants are propagated vegetatively by planting tubers from one generation to the next. When PVY is inoculated to a potato plant, after a multiplication phase in the first infected cells, the virus migrates from cell to cell, cross different cell layers of the inoculated organ and reach the phloem. Once in the phloem, PVY is rapidly translocated to the whole plant including to daughter tubers, where it multiplies. If these infected tubers ('seed' potatoes) are planted the year after, the germinated seedlings will also be infected and usually initiate a rapid PVY dissemination in fields through secondary aphid transmission. Transmission of PVY from mother plants to its 'true' seeds has been reported from *Solanum nigrum*, *Nicandra physaloides* and pepper (*Capsicum annuum*).

The second transmission route corresponds to horizontal transmission from plant to plant by aphids (Fig. 4). PVY displays a large range of aphid vectors. Aphids in 65 species, all in the family Aphidinae, colonizing or not the source plants, were demonstrated to be able to transmit PVY. *Myzus persicae* is the most efficient PVY vector and most of the other aphid species have much lower transmission efficiencies comparatively. Both alate and wingless aphids are vectors of PVY. PVY is transmitted by aphids in a non-persistent manner, meaning that acquisition and inoculation periods are brief (a few seconds or minutes) and that the virus is not retained on the long term by the aphids. Aphid stylets penetrate into the epidermal cell layer of the plants and puncture plant cell membranes, allowing insects to suck the cellular content. In the case of infected cell, this probe or feeding is accompanied by the sucking of virus particles that bind to specific receptors located in the extreme tip of the aphid's stylet, called the acrostyle. Only particles attached to these receptors are involved in aphid transmission. PVY transmission by aphids is also noncirculative. There is no discernible latent period and the virus does not need to circulate into the aphid body to allow transmission. PVY does not pass through insect moults and retention of the virus in the aphid usually lasts not more than 1 or 2 h. However, longer retention periods (up to 17 h in *Aphis nasturtii*) were reported. Prior starvation of the aphids increases the efficiency of transmission though it does not affect the number of electrically-recorded membrane punctures during acquisition periods.

PVY transmissibility is determined by both HC-Pro and CP proteins. The non-structural HC-Pro protein corresponds to the helper component of the aphid transmission, which interacts in its homodimer active form as a bridge between the virion and the aphid stylet. It has been recently proved with other potyviruses that this HC-Pro dimerization is a key step for an efficient transmission. Studies performed on LMV (Lettuce mosaic virus) and TuMV (Turnip mosaic virus) demonstrated that viruses activate their own transmission by dimerization of HC-Pro protein from the moment they perceive an unknown plant signal announcing the penetration of infected cells by aphid vector. Without the presence of this active form of HC-Pro protein, the transmission is impossible. This phenomenon is called the transmission activation (AT). Otherwise, two domains in HC-Pro protein are crucial for PVY transmission: the KITC motif (Lysine/Isoleucine/Threonine/Cysteine) located in its N-terminal region,

which is involved in the binding to a specific receptor in aphid's mouthparts, and the PTK motif (Proline/Threonine/Lysine) in its C-terminal region, which interacts with the DAG motif (Aspartic acid/Alanine/Glycine) at the CP N-terminus. With these two motifs, HC-pro provides the link between the aphid's stylet and the virion.

PVY transmission by pollen has never been proved for any host plant. In experimental conditions, other methods are also used to transmit PVY from plant to plant. The most commonly used is mechanical inoculation. A healthy plant becomes infected by manually rubbing leaves or cotyledons with a mixture containing PVY-infected plant sap and a fine abrasive powder. Transmission by grafting a scion from a virus-infected plant to a healthy stock plant (or vice versa) is also efficient. Transmission of PVY by woundings caused by squashing, squeezing or bouncing of healthy plants in the vicinity of infected plants can happen but is not frequent in field conditions. Transmission of PVY from an infected to a healthy tuber by seed cutting was not reported.

Serology

PVY is considered to be strongly immunogenic. The PVY antigenic structures are carried by the CP. Its C-terminal region contains epitopes specific to PVY, whereas its highly variable N-terminal region carries epitopes allowing the differentiation of PVY in two main serogroups: serotype O (PVY^O, PVY^C, PVY^{N-Wi} strain groups), and serotype N (PVY^N, PVY^{N^{NTN}}, PVY^Z, PVY^E). Antisera and monoclonal antibodies (MAbs) have been produced in rabbits or mice immunized with purified virus preparations or synthetic peptides, or by using DNA-based immunization, or phage display antibody technology. Numerous sources of antibodies and serological detection kits are available. Polyclonal antibodies do not discriminate among PVY strain groups, whereas monoclonal antibodies, triggering a single epitope, allow the serotyping of PVY isolates. These serological reagents have been mainly used in ELISA (Enzyme-Linked Immunosorbent Assay) and related protocols (dot-blot immunobinding assay, immunosorbent electron microscopy, latex and viro-bacterial agglutination tests, immunodiffusion in agar gels) for the detection and the identification of PVY from plant material.

Phylogeny and Evolution

Outside recombinant isolates, three major PVY phylogenetic groups with worldwide distributions, namely C, N, and O, can be distinguished based on genome sequences (Fig. 5). Group C can be further divided into two subgroups, C1 and C2. These phylogenetic groups partly correlate with PVY host specificity. In potato, most isolates belonged to groups C2, N, and O, whereas in pepper (*Capsicum* spp.), most isolates belonged to group C1. All kinds of isolates could be found in tomato or tobacco. A large number of isolates are recombinants between these main phylogenetic groups. Thirty-six different recombination patterns have been identified, mainly between the N and O groups. Such recombinants are now becoming predominant in potato crops worldwide. N × O recombinants are also becoming widespread in pepper crops, whereas isolates from their parental groups are poorly infectious in this crop plant.

Two additional PVY phylogenetic groups were recently identified and have more restricted distributions: a "Chilean" group on tobacco and pepper (*Capsicum baccatum*) and a Brazilian U group on tobacco (Fig. 5). Phylogenetic reconstruction of host specificity in PVY suggests that infection in pepper (*Capsicum* spp.) is a recently-acquired trait and that it was acquired at least twice independently. In contrast, it is uncertain if infection in potato is an ancestral or derived trait in PVY.

PVY belongs to a cluster of 19 potyvirus species, the closest to PVY being Pepper severe mosaic virus. Most of these potyviruses infect plants in the family Solanaceae but others infect plants of the Amaranthaceae, Asteraceae, Liliaceae, Amaryllidaceae, or Verbenaceae.

Fig. 5 Phylogenetic relationships between PVY groups and inference of adaptation to pepper (pep) (A) and potato (pot) (B). (A) The most parsimonious scenario infers that the most recent common ancestor (MRCA) of PVY was not infectious in pepper and get adapted to pepper at least two times independently. (B) There are two equally parsimonious scenarios for PVY adaptation to potato, considering that the MRCA was either infectious (in gray) or not infectious (in black) in potato. Both scenarios involve at least three changes in PVY adaptation to potato. In green: extant PVY clades that are infectious in the respective crop plant. In red: extant PVY clades that are not infectious in the respective crop plant.

PVY in Potato

For almost 50 years, PVY has become the most important virus in most growing areas for seed, ware, and processed potatoes. Serious outbreaks were reported in the 2000s. Tuber quality can be severely affected due to necrosis or defects for processing potatoes. Reduction in size and number of harvested tubers can result in losses up to 80% if no control of PVY spreading was used. Symptoms consist of mild to severe mottle, often associated with crinkling of the leaves (**Fig. 6(A)**). Yellowing and necrosis (vein necrosis and necrotic spots) frequently occur in the lower leaves (**Fig. 6(B)**). Symptoms also include collapse and dropping of intermediate leaves, which remain clinging to the stem (leaf drop). Secondarily-infected plants (when infected tubers are planted) are stunted with crinkled and smaller leaflets.

Necrosis on and around leaf veins, on petioles, stems, and tubers may occur in numerous cultivars. Some necroses on stems and petioles are called stipple-streak disease. The potato tuber necrotic ringspot disease (PTNRD) is characterized by particular patterns on leaves (sometimes oak-leaf necrosis) (**Fig. 6(C)**) and stems, and superficial annular and arched necroses on tubers, first slightly protruding from tuber skin, then becoming dark brown with sometimes crackings of tuber skin (**Fig. 6(D)**).

Potato PVY isolates are classified according to three criteria: their capacity to induce necrotic symptoms on *N. tabacum*, to overcome different resistance genes in *Solanum tuberosum* and to produce necrosis on potato tubers. Based on these biological features, PVY isolates are divided into seven strain groups: PVY^O, PVY^C, PVY^N, PVY^{NTN}, PVY^{N-Wi}, PVY^Z, PVY^E. Besides these strain groups, several individual isolates sharing particular biological properties are till now unclassified. PVY^O and PVY^C induce mosaic symptoms on tobacco leaves. They are mainly separated on the basis of hypersensitive reactions (HR) in potato cultivars. PVY^O induces a HR reaction in cultivars bearing the resistance genes *Ny_{1br}*, *Ny-1* and *Ny-2* (**Table 1**), whereas PVY^C elicits HR response in cultivars carrying the *Nc* gene. PVY^N differs from PVY^O and PVY^C in causing a veinal necrosis in *N. tabacum* cv. Samsun or cv. Xanthi and eliciting a HR in cultivars carrying the *Ny-1* and *Ny-2* resistance genes (**Table 1**). Two aa at positions 400 and 419 in the HC-Pro protein are involved in the induction of the necrotic reaction in tobacco.

Isolates of the PVY^{NTN} group express the same biological feature as PVY^N, except that they are able to induce tuber necrosis on susceptible cultivars. One of the viral molecular determinants inducing PTNRD was identified at aa position 419 in the HC-Pro protein, but some others are still unknown. Whole genome analyses of PVY^{NTN} isolates revealed that most of them result from three to four recombination events between PVY^O and PVY^N isolates, with breakpoints being not exactly at the same nucleotide position. Some PVY^{NTN} isolates however are not recombinants (**Fig. 7**).

Table 1 Molecular determinants of pathogenicity and transmission identified in PVY

Phenotype	Plant	Genome region	Mutation
<i>Pathogenicity</i>			
Veinal necrosis	<i>Nicotiana tabacum</i>	Hc-Pro	N339D, D400K, D419E
Veinal necrosis	<i>Nicotiana tabacum</i> with the <i>Rk</i> nematode resistance gene	Nib	–
Tuber necrosis	<i>Solanum tuberosum</i>	HC-Pro	D419E
Leaf necrosis	<i>Physalis floridana</i>	CP	–
<i>Host range</i>			
Systemic infection	<i>Capsicum annuum</i>	P3 and/or P3N-PIPO	N131Y, N131F
Systemic infection	<i>Capsicum annuum</i>	CI	–
<i>Interaction with plant resistance</i>			
Resistance induction	<i>Solanum tuberosum</i> with the <i>Nc</i> resistance gene	Hc-Pro	K269R and/or R270K (local necrosis induction)
Resistance induction	<i>Solanum tuberosum</i> with the <i>Ny</i> resistance gene	Hc-Pro	K269R and/or R270K (necrosis induction)
Resistance breakdown	<i>Capsicum annuum</i> with the <i>pvr2</i> resistance gene	VPg	Different mutations in codons 101–123
Resistance breakdown	<i>Capsicum annuum</i> with the <i>pvr2³</i> resistance allele	VPg and CI	–
Resistance breakdown	<i>Capsicum annuum</i> with the <i>Pvr4</i> resistance gene	Nib	K472E
Resistance breakdown	<i>Solanum lycopersicum</i> with the <i>pot – 1</i> resistance gene	VPg	R119H
Resistance breakdown	<i>Nicotiana tabacum</i> with the <i>va</i> resistance gene	VPg	105E, 105T, 105M, 119A
Loss of resistance induction	<i>Solanum tuberosum</i> with the <i>Ry</i> resistance gene	Nla-Pro	H46Y, D81A, C151F or H167P
<i>Aphid transmission</i>			
Loss of transmissibility		Hc-Pro	K59E
Increase of transmissibility		CP	E68K

Note: “–”: unavailable data.

Isolates of the PVY^{N-Wi} group, similar to PVY^{N-O} in North America, are differentiated from PVY^N isolates by their O/C (instead of N) serotype, and by their capacity to induce PTNRD on specific cultivars. The fact that these isolates share both PVY^N and PVY^O properties is due to the presence of two to four recombination breakpoints in their genome leading to a succession of O- and N-type nucleotide sequences (Fig. 7). PVY^Z and PVY^E isolates are closely related to PVY^{NTN} isolates because they cause PTNRD in tubers and display a similar recombinant genome, but they differ by their capacity to induce mosaic symptoms in tobacco leaves, as PVY^O isolates. Moreover, PVY^Z isolates elicit a HR reaction in potato cultivars carrying the *Nz* resistance gene, which is not the case of PVY^E isolates.

The first PVY groups identified in the early 1930s were PVY^C and PVY^O, and PVY^N a few years later. In contrast to PVY^C which became less frequent in potato, PVY^O remained the dominant group in potato fields up to the 2000s. However, from the 1960s, infections caused by PVY^N isolates increased progressively in Europe and became dominant 40 years later. This change was associated to the emergence of PVY^{NTN} isolates, which were first described in Hungary in 1982 and soon spread in most potato growing countries, except in North America where they were classified as quarantine pathogens. So far, PVY^{NTN} isolates have a worldwide distribution and are predominant notably in Europe. In Switzerland and Estonia, a significant decrease in the occurrence of PVY^{NTN} isolates was recently observed concurrently with an increase of PVY^{N-Wi} infections, probably due to a change in potato varieties. PVY^{N-Wi} isolates were identified for the first time in Poland in 1984 and they are currently present throughout the world with varying frequencies. Some surveys performed these last two decades reported that PVY^{NTN} and PVY^{N-Wi} groups have almost replaced the PVY^O and PVY^N ancestral groups in many countries. PVY^Z and PVY^E groups are not frequent.

Differences in aphid transmission between strains were reported. PVY^N isolates seem better transmitted than other PVY isolates with longer retention periods in aphids. Whatever the strain, *Myzus persicae* is clearly the most important vector in most potato-growing areas. However, despite their low transmission efficiency, other species colonizing potatoes such as *Aphis nasturtii*, or visiting potatoes can also contribute to PVY spread. Some of these species, notably cereal aphids or the pea aphid, seem to be involved in PVY epidemics in potato crops in Europe and the USA due to their high abundance.

Control Methods

Control methods are first based on sanitary control of seed potatoes and breeding for resistance, especially regarding PVY^N. Sophisticated schemes of seed production include monitoring of aphid vectors, treatments by mineral oils against aphid transmission, eradication of weeds, and post-harvest detection tests using large-scale ELISA. Numerous molecular assays were also developed for PVY detection in leaves, potato tubers, and aphids, including numerous RT-PCR protocols, microarray technology, and real-time RT-PCR methods. Resistance based on hypersensitive reaction (HR) and extreme resistance (ER) against PVY are

Fig. 7 Schematic representation of the main molecular diversity within potato PVY strain groups. Boxes in white, brown and black correspond to PVY^O, PVY^C and PVY^N nucleotide sequences, respectively. RJ1, RJ2, RJ3 and RJ4 correspond to the position of the hot spots of recombination described in PVY genome. “Other” refers to some PVY isolates displaying particular biological properties. The arrow indicates the presence of single nucleotide mutation leading to a serological misidentification. Adapted from Glais, L., Bellstedt, D.U., Lacomme, C., 2017. Diversity, characterization and classification. In: Lacomme, C., Glais, L., Bellstedt, D.U., *et al.* (Eds.), Potato Virus Y: Biodiversity, Pathogenicity, Epidemiology and Management. Switzerland: Springer, pp. 43–76.

largely used. HR is based on the single dominant genes *Nc*, *Nz* and *Ny* and ER is based on the *Ry* genes. The *Ry* genes (*Ry_{adg}*, *Ry_{chr}*, *Ry(o)phu*, *Ry_{sto}*), from wild *Solanum* species, map on chromosomes 11, 9, 9, and 12, respectively, and confer broad-spectrum resistance, whereas HR genes *Nc*, *Ny_{thr}* (which map on chromosome 4) and *Nz* found in old potato cultivars, protect against PVY^C, PVY^O, and PVY^Z, respectively. More recently, *Ny-1* and *Ny-2* genes eliciting hypersensitive response against both PVY^C and PVY^N isolates were mapped on potato chromosomes 9 and 11, respectively. Beside these well documented resistance genes, new putative resistance genes were reported according to local symptoms observed on leaves inoculated with a set of differential PVY strains. *Nw*, *Ne*, *Nn*, *Nna* seem to confer resistance against PVY^{N-Wi} (or PVY^{N-O}), PVY^E, PVY^N, and PVY^N from North America, respectively (Table 2). Sources of resistance against aphids were identified in wild *Solanum* species but not introgressed in potato cultivars yet.

PVY in Pepper

PVY is the causal agent of major diseases and production losses in pepper crops. PVY affects pepper production worldwide, while other pepper-infecting potyviruses, like Tobacco etch virus, Pepper severe mosaic virus, Pepper yellow mosaic virus, Pepper vein mottle virus or Chilli vein mottle virus are mostly restricted to particular continents and are not present in Europe. Symptoms are mostly visible on the vegetative parts of the plants but rarely on fruits. Depending on the pepper genotype and on the virus isolate, they consist of mosaic and vein banding on leaves or necrotic symptoms on leaves, petioles, and stems (**Fig. 8(A)** and **(B)**).

The most widespread and efficient way to control PVY in pepper is through the growing of cultivars carrying resistance genes. The first resistance genes used to control PVY were the *pvr2*¹ and *pvr2*² alleles, which control high-level resistance since no virus can be detected in inoculated organs of the plants. These genes have been exploited for decades in a large number of pepper cultivars and proved to be durable. However, PVY isolates virulent to the *pvr2*¹ allele were occasionally observed, especially in the Mediterranean basin and in tropical regions, while isolates virulent to the *pvr2*² allele are exceptional.

Table 2 List of identified PVY resistance genes in various hosts

Carrier chromosome	Gene or allele name	Nature of encoded protein	Source of resistance
<i>Potato</i>

Chr. 3	<i>pot – 1²</i>	eIF4E	<i>Solanum pimpinellifolium</i> 'LA0411'

Note: eIF4E: eukaryotic initiation factor 4E; NLR: nucleotide-binding leucine-rich repeats.

“–” corresponds to unknown data.

These two alleles and the wild-type susceptibility allele *pvr2*⁺ encode different copies of the eukaryotic translation initiation factor 4E1 (eIF4E1) that differ by a few amino acid substitutions. Reciprocally, amino acid substitutions in the central part of the VPg of PVY determine the virulence towards *pvr2* alleles. In addition to *pvr2*¹ and *pvr2*², more than 30 *pvr2* resistance alleles are found in locally-grown pepper accessions of almost all *Capsicum* species analyzed. Most of these alleles have a specific resistance spectrum that match PVY VPg diversity. The large amino acid diversity in both pepper eIF4E1 and PVY VPg and evidence of positive selection during the evolution of these two proteins suggest a co-evolution between pepper and PVY. Pepper infection and resistance based on eIF4E1/VPg interaction obey a lock-key model: direct binding between eIF4E1 and VPg proteins allows PVY to replicate and translate its genome and to infect the plant. In contrast, amino acid substitutions in either the eIF4E1 or VPg that abolish binding are responsible for plant resistance. There are great differences in durability for the resistance conferred by different *pvr2* alleles.

From the 1990s, the dominant *Pvr4* gene, originating from a Mexican *C. annuum* population, was introgressed into bell-pepper cultivars. This gene confers a high-level resistance to all tested isolates of PVY in addition to five other potyviruses belonging to the PVY phylogenetic group: EcRV (Ecuadorian rocoto virus), PepMoV (Pepper mottle virus), PepSMV (Pepper severe mosaic virus), PepYMV (Pepper yellow mosaic virus), and PTV (Peru tomato mosaic virus). This resistance shares common properties with hypersensitivity-based resistances. Only a few laboratory-selected PVY isolates are able to break down the *Pvr4* resistance, indicating a high durability of the resistance. The *Pvr4* gene was shown to encode a nucleotide-binding and leucine-rich (NLR) domain protein. It shares common structure and sequence with the *Tsw* gene that confers resistance to Tomato spotted wilt virus, suggesting a common origin. The ability of laboratory isolates to break the *Pvr4* resistance was shown to be due to a single substitution in the NlB coding region. This mutation induces a high competitiveness cost to PVY in plants devoid of the *Pvr4* gene, which may explain the high durability of this resistance.

Other pepper resistances to PVY have been described but not used in commercial cultivars. A polygenic resistance from the *C. annuum* accession Perennial was analyzed and several QTLs (quantitative trait loci) have been mapped in the plant genome. These QTLs can be used in combination to a *pvr2* resistance allele to improve its durability. The *Pvr7* resistance gene from the *Capsicum chinense* accession PI159236 confers a high level of resistance to PVY and PepMoV and is allelic to *Pvr4*.

Other control measures such as the use of oil sprays or physical barriers (polyethylene sheets and coarse nets) were also used for controlling spread of PVY in pepper crops in Israel and Florida.

PVY in Tomato

PVY can induce severe diseases in tomato crops but has long been considered a pathogen of secondary importance, inducing mild mosaic on the foliage only. Since the 1980s, new strains of PVY have arisen in Mediterranean countries, causing serious

Fig. 8 PVY infection in a pepper field: (A) severe crinkling and distortion of the leaves. (B) Necrotic patterns on a leaf. Most pepper isolates of PVY belong to the C1 phylogenetic group, but more and more N/O recombinants are observed. An O/C recombinant strain inducing veinal necrosis was also isolated in pepper in Italy. PVY infection on tobacco cv. Burley in field trials in Southwestern France. (C) Chlorotic oak-leaf and halo patterns. (D) Severe systemic necrosis. Photographs: P. Gognalons, (A) and M. Pepelnjak Slovenia (B), Blancard (C) and (D), INRAE, France.

yield and quality loss of tomato fruits. These strains induce necrotic lesions on leaves and necrotic streaks on stems in all tomato varieties and frequently affected 100% of the plants in greenhouses as well as in open fields. Importantly, combination of PVY infections with other viruses such as Cucumber mosaic virus can induce very severe diseases in tomato crops. Data about the genetic diversity of PVY isolates from tomato are scarce. Isolates belonging to the C1, N, O, and N/O groups have been observed in tomato crops. In laboratory tests, most of the isolates belonging to all PVY phylogenetic groups induce systemic infections in tomato.

There are few reports about PVY resistance in tomato and related species. Accession PI247087 of *Solanum habrochaites* was described highly resistant to PVY. The resistance is efficient toward all tested PVY isolates, inhibits the multiplication of the virus in the inoculated organs and is controlled by a single recessive gene (named *pot-1*) which is homologous to the *pvr2* gene in pepper and encodes the eIF4E1. Strains of PVY virulent to the *pot-1* resistance can be selected in laboratory tests, a property that is controlled by a single aa substitution in the VPg. The *pot-1* gene was introduced into genotypes of *S. lycopersicum*, but varieties carrying this gene are not widespread, possibly because PI247087 is an accession of the wild species *S. habrochaites* and introgression of the resistance into cultivated tomato is difficult or is deleterious for yield and/or quality.

Accession LA0411 of *Solanum pimpinellifolium* carries also a *pot-1* mutant allele (*pot-1*²) that confers resistance to PVY, but the spectrum of the resistance is narrow (only a few PVY isolates) and its durability potential is low.

Engineered resistance was also developed in tomato (*S. lycopersicum*) using a TILLING (targeting induced local lesions in genomes) approach, which combines ethyl methane sulfonate mutagenesis and gene-specific detection of mutations. An eIF4E1 KO (knock out) mutant showed a narrow spectrum of resistance against PVY. This spectrum was enlarged to all tested PVY isolates (and to Tobacco etch virus isolates) when the eIF4E1 KO mutation was combined with a KO mutation in another gene of the eIF4E family, eIF4E2. However, this double mutant showed a stunted growth.

PVY in Tobacco

PVY was reported to be the most damaging virus in tobacco crops. It causes height reductions and modifies the chemical composition of cured leaves, especially the nicotine content. Yield losses of 14%–59% were reported with incidence of up to 100%. Symptoms on leaves are usually mild mottling but particular chlorotic patterns and necroses, notably the veinal necrosis disease, may also occur (Fig. 8(C) and (D)). PVY isolates are split into two groups according to their capacity to induce (PVY^N) or

not (PVY^O and PVY^C) veinal necrosis on tobacco leaves. As said previously, the HC-Pro was shown to carry molecular determinants involved in this phenotype. Recently, the *RPP8-like* gene in tobacco, called *NtTPN1* (*Nicotiana tabacum* Tolerance to PVY-induced Necrosis1), was shown to determine the expression of the necrotic symptoms, presumably through direct or indirect interaction with viral HC-Pro protein, because the Glycine to Arginine mutation at codon position 497 in *NtTPN1* is sufficient to suppress PVYN-induced veinal necrosis. Genome analyses of PVY isolates collected in tobacco in different countries reported that O, N, and C1 isolates as well as N/O recombinants (PVY^{NTN}, PVY^{N-wi}) are found on tobacco.

Breeding for resistance is the main control method against PVY in tobacco production. Many European and American commercial cultivars carry recessive resistances of varying efficiency and durability. The *va* gene of the Virgin A Mutant (VAM) line, corresponding to a large deletion around the *elF4E-1* gene on chromosome 21 after X-ray irradiation, has been extensively used, though its introgression is often associated with a decrease of yield and cured leaf quality. Nevertheless, some *va*-breaking necrotic PVY isolates were observed in open fields. Recently, it was reported that the durability of this resistance is enhanced by a complex genetic locus on chromosome 14 containing three other *elF4E* genes. The viral VPg protein is involved in the breakdown of the resistance conferred by *va* (Table 1).

In countries where early infection occurs frequently, additional measures consist in protecting seedbeds by fleece, eradication of weeds and isolation from potato, tomato and pepper fields. Pathogen-derived resistance has been extensively studied in tobacco, although more for investigating the mechanisms of protection than for use in commercial tobacco cultivars.

Prospects

Since the first identification of PVY, a significant amount of information was collected by researchers. However, some gray areas remain in understanding the complexity of the interaction between PVY and its hosts and its vectors: How to explain the emergence and prevalence of PVY recombinants in crops? How is PVY aphid transmission activated? What are the plant and virus molecular determinants involved in pathogenicity (symptoms, resistance breakdown or induction)? How to better understand and exploit resistance genes against PVY? Are aphids the only insects to transmit PVY? A better understanding of the plant/PVY/vector pathosystem would allow us to control better PVY epidemics.

Glossary

Jacalin-type lectin 1 (JAX1) Antiviral resistance gene to Potato virus X related to lectin – mediated resistance (LMR) confers plant innate immunity against viruses.

RNA silencing suppressor Plant viruses have encoding protein to counteract the plant antiviral system known as RNA silencing.

Rx protein A highly similar CC-NBS-LRR protein, which prevents virus accumulation, mediates extreme resistance against PVX.

Triple gene block The protein comprises of a substantially similar element of three partially overlapping ORFs and is contained within their genomes. The TGB proteins are correlated with cell-to-cell movement and potentially influence on host antiviral defenses.

Introduction

A genus *Potexvirus* is one of seven genera in the family *Alphaflexiviridae*. Most potexviruses are found wherever their hosts are grown. The genus *Potexvirus* contains 38 definitive species including 35 species determined complete genome sequences. The genomes of Cassava virus X (CsVX) and Lagenaria mild mosaic virus (LaMMoV) have been partially sequenced and that of Plantain virus X (PIVX) has yet been reported. There are also 5 tentative species for which genomic sequences are available, but they have not yet been accepted by ICTV (**Table 1**). The members of the genus *Potexvirus* can be divided into three main phylogenetic groups based on their genome sequences. The phylogenetic relationships of the genus *Potexvirus* are not associated with their natural host other than cactus-infecting viruses. The virions of the genus *Potexvirus* have non-enveloped and flexible particles of 470–1000 nm in length and 12–14 nm in diameter. Their genomes of 5.8–7.2 kb in length consist of a positive-sense single-stranded RNA (ssRNA) with 5' terminal cap structure and a 3' terminal poly(A) tail. The genomes encode for an RNA-dependent RNA polymerase (RdRp) for viral replication, a triple gene block (TGBp1, 2, and 3) for viral movement, and a coat protein (CP). The RdRp is associated with jacalin-type lectin required for potexvirus resistance 1 (JAX1)-mediated resistance of host plant. The TGBp1, known as viral suppressors of RNA silencing, acts an avr protein associated with an HR-like response. Host plants naturally infected with potexviruses may show mosaic, mottle, necrosis, chlorosis, spots, or dwarf symptoms or may be symptomless. The natural host range of individual viruses is usually restricted to a few plant species, although a few of the viruses can infect a wide range of plant species. Potexviruses are transmitted mechanically through contact with virus-infected plant sap, or with contaminated agricultural equipment. Most potexviruses are not transmitted by vertebrate, invertebrate, or fungal vectors; Strawberry mild yellow edge virus (SMYEV) and Potato aucuba mosaic virus (PAMV) are transmitted by aphids. The type species of the genus *Potexvirus* is *Potato virus X* (PVX). During the last few decades, PVX has greatly contributed to our understanding of host resistance and gene silencing mechanisms, in particular because of the use of viral vectors in studying gene expression and RNA silencing in plants.

Table 1 Virus species in the genus *Potexvirus* of the family *Alphaflexiviridae*. Type species in the genus is written in bold. Complete sequences accession number and length (nt) of the genomes are indicated (ICTV, 2019)

^aIncomplete genome sequence.

Taxonomy, Phylogeny, and Evolution

The genus *Potexvirus* is one of seven genera in the family *Alphaflexiviridae*. Its name is derived from *Potato virus X* (the type species of potexviruses). The genus contains 39 definitive species, of which 36 have complete genome sequences (Table 1). The complete genome sequences of some members have recently been determined. The genomes of Cassava virus X (CsVX) and LaMMoV have been partially sequenced. The genome sequences of PIVX has yet been reported. Another 4 tentative species have genomic sequences available, but they have not yet been accepted by ICTV (Table 1). Phylogenetic analysis using the complete genome sequences of the 36 potexviruses of their RNA-dependent RNA polymerase (RdRp), has revealed that they can be divided in seven major branches from I to VII (Fig. 1). Phylogenetic analysis of the complete sequences of the same 36 potexviruses of their coat protein (CP), (Fig. 1) and their triple gene block (TGB) proteins (Fig. 2), are showing that the seven clusters, with only a few exceptions, can be identified for all the proteins with the except for the TGBp3, which is showing a major reorganization of the potexvirus diversity. However it is also important to note that the TGBp3 phylogenetic tree is not very stable as only 5 branches have a bootstrap value above 50%. This result seems to indicate that there has been a co-evolution of the genes/proteins composing the potexvirus genome, with perhaps the exception of TGBp3. These

Fig. 1 Phylogenetic analysis of genus *Potexvirus* based on the amino acid sequences of the RdRp and CP. Multiple sequence alignments were generated using DNAMAN software version 5.1 (Lynnon Biosoft, San Ramon, Ca, USA) and phylogenetic trees were constructed by the neighbor-joining algorithm, based on calculations from pairwise amino acid sequence distances for protein analyses derived from the multiple alignment format. The horizontal branch lengths are proportional to the genetic distance, and the numbers at each point indicate bootstrap values. The dataset was subjected to 10,000 bootstrap replicates and values above 50% are indicated on the branches. Virus names are indicated by their abbreviation and their full names are in [Table 1](#). NCBI database accession numbers follow the virus abbreviation name. The black vertical bars identify the seven major clusters (from I to VII) as defined per the RdRp phylogenetic tree and differential colored boxes are shown in each tree.

phylogenetic trees do not show a correlation of the viruses with their type of host with the exception of the cactus-infecting viruses such as Cactus virus X (CVX), Pitaya virus X (PiVX), Opuntia virus X (OpVX), Schlumbergera virus X (SchVX), and Zygocactus virus X (ZyVX) that are grouped together in each tree (cluster III).

The species demarcation criteria in the genus *Potexvirus* are the followings: (1) members of distinct species have less than 78% nt or 61% aa identity of their RdRp, less than 73% nt or 73% aa identity of their TGBp1, less than 65% nt or 64% aa identity of their TGBp2, less than 66% nt or 59% aa identity of their TGBp3, and less than 57% nt or 49% aa identity of their CP; (2) members of distinct species are readily differentiated by serology, and some virus strains can be differentiated with monoclonal antibodies; and (3) members of distinct species fail to cross-protect in common host plant species, and they usually have distinguishable experimental host ranges.

Virion Structure

Virions are non-enveloped and flexible filaments of 470–1000 nm in length and 12–14 nm in diameter ([Fig. 3](#)). They have helical symmetry with a pitch of 3.3–3.6 nm. The number of protein subunits per turn of the primary and final symmetries is slightly less than 9.0. The viral RNA is at a radius of 3.0–3.5 nm. Virion Mr is about 3.5×10^6 with 5%–7% nucleic acid content. PVX virion is a filamentous particle of about 515 nm in length and 13.5 nm in diameter and forms a helical array (3.5 nm pitch) of about 1300 identical CP subunits with the viral RNA packed between turns of the helix. The virion has 8.9 CP subunits, each consisting of 236 aa residues, per primary helix and five nucleotides are related to each protein subunit. The viral RNA molecule have about 6% by weight of the virion. Narcissus mosaic virus (NWV) helix has eight subunits per turn and an outer radius of 5.5 nm. The assembly of potexvirus ribonucleoproteins does not depend on the RNA nucleotide sequences.

Fig. 2 Phylogenetic analysis of genus *Potexvirus* based on the amino acid sequences of the TGBp1, TGBp2, and TGBp3. Multiple sequence alignments were generated using DNAMAN software version 5.1 (Lynnon Biosoft, San Ramon, Ca, USA) and phylogenetic trees were constructed by the neighbor-joining algorithm, based on calculations from pairwise amino acid sequence distances for protein analyses derived from the multiple alignment format. The horizontal branch lengths are proportional to the genetic distance, and the numbers at each point indicate bootstrap values. The dataset was subjected to 10,000 bootstrap replicates and values above 50% are indicated on the branches. Virus names are indicated by their abbreviation and their full names are in [Table 1](#). NCBI database accession numbers follow the virus abbreviation name. The black vertical bars identify the seven major clusters (from I to VII) as defined per the RdRp phylogenetic tree and differential colored boxes are shown in each tree.

Genome Organization

The genome of potexviruses is a sense single-stranded positive-sense RNA (ssRNA) with 5' terminal cap structure and a 3' terminal poly (A) tail. The genome of 5.8–7.2 kb in size contains five ORFs (encoding an RdRp), three movement proteins called TGB, and the CP from the 5' to the 3' end ([Fig. 5](#)). The genome organization resembles that of genera *Foveavirus* and *Robigovirus* in the family *Betaflexiviridae*, but is distinguishable from them by the size of genome (8–9.3 kb). The complete genomic sequences of almost all potexviruses has been determined ([Table 1](#)). The genome structure of PVX is showed in [Fig. 4](#). The genome consists of 6435 nt and contained five ORFs coding for the proteins of an RdRp of 166 kDa (ORF1; 4371 nt), a TGBp1 of 25 kDa (ORF2; 681 nt), a TGBp2 of 12 kDa (ORF3; 348 nt), a TGBp3 of 8 kDa (ORF4; 213 nt), and a CP of 25 kDa (ORF5; 714 nt) from the 5' to 3' end. Both terminal regions of ORF3 (12 kDa) shows overlap with ORF2 and ORF4, respectively. The 5' terminal region of ORF5 shows an overlap with ORF3. The lengths of the 5' non-translated region (NTR) and the 3' NTR have 84 and 73 nt. The 3' NTR region contains the poly(A) tail. Some potexviruses eg, Actinidia virus X (AVX); Alstroemeria virus X (AlsVX); Cymbidium mosaic virus (CymMV); NMV; PVX; SMYEV; White clover mosaic virus (WClMV), have a putative ORF6 located within the ORF5 or over the ORF5 and 3' NTR. Bamboo mosaic virus (BaMV) is frequently associated with a satellite RNA (satRNA). The satRNA is a linear RNA of 836 nt and comprises a single ORF encoding a 20 kDa protein.

Fig. 4 Genome organization of Potato virus X, the type species of the genus *Potexvirus*. RNA-dependent RNA polymerase (166 kDa) (green box) includes a methyl-transferase (Met), a helicase domain (Hel), a polymerase (Pol) domains. Purple boxes indicate the triple gene block corresponding to three overlapping ORFs (TGBp1, TGBp2, and TGBp3), and ORF5 encodes the CP (orange box).

Fig. 5 Symptoms of potexvirus-infected plants. (A) *Malva* spp. infected with Malva mosaic virus (MalMV) exhibiting symptom of mosaic on leaves. (B) *Hydrangea* spp. infected with Hydrangea ringspot virus (HdRSV) exhibiting symptoms of chlorotic and necrotic ringspots on leaves. (C) *Lilium* spp. infected with Plantago asiatica mosaic virus (PIAMV) exhibiting symptoms of brown necrotic streaking and irregular chlorosis on leaves. (D) *Solanum lycopersicum* infected with Pepino mosaic virus (PepMV) exhibiting symptoms of open fruit. (E) *Bambusa vulgaris* infected with Bamboo mosaic virus (BaMV) exhibiting symptoms of interveinal chlorotic mosaic and stripes on leaves. (F) *Dendrobium phalaenopsis* infected with Cymbidium mosaic virus (CymMV) exhibiting symptoms of chlorotic and necrotic ringspots on leaves.

Properties and Functions of Gene Products

The RdRP of potexviruses contains three conserved domains: a methyl-transferase (Met) domain; an RNA helicase (Hel) domain; a polymerase (Pol) domain. The RdRP is related to jacalin-type lectin required for potexvirus resistance 1 (JAX1)-mediated resistance of host plant. The cell-to-cell movement of potexviruses requires the potexviruses TGB and CP. TGBp1 and CP form a complex with viral RNA that transfers to the next cell via the plasmodesmata. The TGBp1 also acts as viral suppressors of RNA silencing and an avr protein

associated with an HR-like response. It has been recently demonstrated that PVX TGBp1 interacts with the chloroplast protein ferredoxin 1 (FD1) related to its role in the chloroplast electron transport chain. The TGBp1 of Pepino mosaic virus (PepMV) is associated with a thioredoxin domain-containing protein that is related to virus movement. TGBp2 and TGBp3 are endoplasmic reticulum-binding proteins for virus movement. The TGBp2 is also associated with a functional role in PVX replication. BaMV TGBp2 interacts with a *Nicotiana benthamiana*-expressed thioredoxin type h protein (*NbTRXh2*), which acts as a negative regulator of viral movement. CP is required for virion assembly. PVX CP is the elicitor for Rx-mediated resistance that impairs virus accumulation in host plant. The CP of Potato aucuba mosaic virus (PAMV) has a DAG motif associated with aphid transmissibility, located in the aa residues 14–16 from the N-terminus of the CP, which is also found in the CP of potyviruses. Satellite RNA (satRNA), with crucial roles in modulating viral replication and symptom development, is associated with BaMV and it was found to be the only satRNA of the genus *Potexvirus*. The RNA-binding domain of PAMV CP, located between 90 and 130 aa, is associated with virion assembly.

Replication and Propagation

The 5' NTR regulates plus-strand RNA synthesis, sub-genomic RNA synthesis, cell-to-cell movement, and virion assembly. Two RNA stem-loop (SL) structures within the 5' NTR, named 5' SL1 and 5' SL2, are required for viral replication. The 5' SL1 is a multifunctional element associated with virus replication, gene expression, cell-to-cell movement, and virion assembly. RdRP can be translated directed from the genomic RNA and then three sub-genomic RNAs are generated for TGB and CP synthesis. The 3' NTR including three RNA stem-loop structures, named 3' SL1, 3' SL2, and 3' SL3, controls minus-strand and plus-strand RNA accumulations. The 3' NTR has multifunctional activities, related to viral replication and host-factor interaction. The RNA replication and accumulation of PVX interact synergistically with potyviruses (Pepper mottle virus, Plum pox virus, Potato virus Y, Tobacco vein mottling virus, and Tobacco etch virus). The PVX/potyviral-associated synergism is related to the 5' proximal potyviral sequence and microRNAs derived from co-infected plants. The 5' NTR of satRNA, which associated with BaMV, acts as a regulator of BaMV replication. The transgene induced from potexvirus-based vector can be stably expressed as a N-terminal translational CP fusion linked by the autocatalytic 2A peptide, which is derived from foot-and-mouth disease virus.

Transmission, Host Range

Potexviruses can be naturally transmitted to various horticultural crops. Most potexviruses can be transmitted mechanically via contact with virus-infected plant sap, or with contaminated agricultural equipment. PAMV and PVX cause common symptoms in *Solanum tuberosum* grown worldwide. PAMV exhibiting slight leaf mottling on *S. jasminoides* causes yellow leaf flecking, deformation, and stunting on susceptible potato plants. PVX cause mild mosaic, necrosis, or is symptomless on potato plants and can be co-infected with Potato virus Y and *Candidatus phytoplasma trifolii* on *S. melongena*. Five viruses, CVX, OpVX, PiVX, SchVX, and ZyVX, cause mild mosaic, mosaic, necrosis, ringspots or are symptomless on *Cactaceae*. The CVX, OpVX, SchVX, and ZyVX can be transmitted by mechanical inoculation. LVX, PIAMV, and Tulip virus X (TVX) can be naturally transmitted to *Lilium* spp. The PIAMV can cause mosaic and necrosis on *Plantago asiatica* and *Solanaceae*, as well as *Lilium* spp. The TVX can cause chlorotic and necrotic spots of leaves and streaks of petals in *Lilium* spp. and *Tulipa* spp. The LVX appears to be asymptomatic in *Lilium* spp. Cassava common mosaic virus (CsCMV) and CsVX can be naturally transmitted to *Manihot esculenta* and these viruses can be mechanically transmitted to *N. benthamiana*. The CsCMV causes mosaic and chlorosis on *M. esculenta* while the CsVX exhibits no symptoms. Clover yellow mosaic virus (CIYMV) and WCIMV can be naturally transmitted to *Trifolium* spp. The CIYMV causes chlorotic streaks of leaves and color breaking of flowers on *T. gesneriana* and it causes yellow mosaic or is symptomless on *T. repens*. CymMV causes chlorotic or necrotic spots on the leaves and flowers of orchid plants. The flowers infected with the CymMV exhibit deformation and color breaking. CymMV has also been associated with flecking on leaves, necrotic spots on the stem, and vine decline of vanilla plants. Papaya mosaic virus (PapMV) causes mosaic and stunting on *Carica papaya* while it exhibits no symptoms on *Ullucus tuberosus*. PepMV can be naturally transmitted to greenhouse tomato species (*S. lycopersicum*) and wild tomato species (*S. chilense*, *S. chmielewskii*, *S. parviflorum*, and *S. peruvianum*) and it causes fruit marbling and discoloration, open fruit, nettle-heads, leaf blistering or bubbling, leaf chlorosis and yellow angular leaf spots, leaf mosaic and leaf or stem necrosis in susceptible tomato plants. SMYEV causes marginal yellowing symptoms on leaves of commonly cultivated strawberry crops in worldwide. LVX, SMYEV, PAMV, and PepMV can be transmitted by aphids. Hosta virus X (HVX) can be naturally transmitted to *Hosta* spp. and cannot be transmitted mechanically to *N. benthamiana* and *N. clevelandii*. HVX and PepMV can be transmitted by seeds. BaMV can be transmitted by dipterans (*Gastrozona fasciventris* and *Atherigona orientalis*). Some viruses are not transmitted by mechanical inoculation. Allium virus X (AIVX) causes diffuse yellow stripes or mottle on leaves of *Allium* spp. Yam virus X (YVX) causes mild chlorosis on leaves of *Dioscorea trifida*. The methods for transmission of three potexviruses, such as AIVX, PiVX, and YVX, are presently not known.

Epidemiology and Control

Most potexviruses can cause usually mild mosaic, mosaic, chlorosis, spots, or symptomless in their host plants. Some food and ornamental crops sustain economic damage caused by potexviruses that require suitable disease management. Transgenic cactus,

orchid, potato, and tobacco plants, which are resistant to BaMV, CymMV, CVX, PVX, and SMYEV respectively, have been developed. PVX can cause yield losses reaching 20% of productivity depending upon the virus strain. New potato varieties carrying the *Rx1* and/ or *Rx2* genes derived from the wild species *Solanum tuberosum* ssp. *andigena* and *S. acaule*, respectively, have been developed to control the virus. Salicylic acid has been demonstrated to mitigate physiological and proteomic changes caused by PVX (SPCP1 strain) in tomato. CsCMV has been found in cassava, which grows in the Americas. The CsCMV can cause a reduction of up to 60% of root productivity. CymMV has been reported in most cultivated orchid species grown in worldwide since it was first described on *Cymbidium* in California. The virus has also been found in vanilla from most growing areas since it was first detected in vanilla (*Vanilla* spp.) in the Society Islands (1987). Skimmed milk represented inactivation of CymMV on local host, but has not been evaluated on systemic host. RNA silencing is an important defense mechanism against plant viruses and it has been applied to control potexviruses. The potexvirus TGBp1, is known as RNA silencing suppressor, and it has been used frequently for producing virus-derived small interfering RNAs. PLAMV has been isolated from various species worldwide (eg, *Achyranthes bidentate*; *Lilium* spp.; *Nandina domestica*; *Primula sieboldii*; *Rehmannia glutinosa*; *Stellaria media*; *Urtica urens*; *Viola grypoceras*), since it was first reported from *Plantago asiatica* grown in Russia (1976). This viral disease is especially known to reduce considerably the commercial value of lilies. Early bulb test of the viral infection should be carried out in order to control the virus in greenhouse. PepMV causes a severe disease in greenhouse tomato crops worldwide, since it was found in the Netherlands. The factor associated with the epidemiology of the PepMV can be dependent on the properties of the different virus strains. The virus is currently controlled using virus-free seeds. SMYEV has often been found in co-infection with other viruses, such as Arabis mosaic virus (ArMV, genus *Nepovirus*), Strawberry crinkle virus (unclassified within the family *Rhabdoviridae*), Strawberry mottle virus (unclassified within the family *Secoviridae*), Strawberry polerovirus 1 (unclassified within family *Luteoviridae*), Strawberry pallidosis-associated virus (unclassified within the family *Closteroviridae*), or Tomato ringspot virus (ToRSV, genus *Nepovirus*), and the viral co-infection can significantly reduce the yield of cultivated strawberry crops grown in greenhouses. Chemotherapy with ribavirin has recently been tested to control of the ArMV, SMYEV, and ToRSV.

Diagnosis

Potexviruses can be detected by polymerase chain reaction (PCR)-based methods, such as reverse transcription (RT)-PCR, immunocapture-RT-PCR, loop-mediated isothermal amplification (RT-LAMP) assay, multiplex RT-PCR, and real-time PCR. Some commercial antisera are used for immunological detection of potexviruses. Lateral flow immunoassay (LFIA) used with alkaline phosphatase has been developed for PVX detection and it has a lower limit of detection (0.3 ng/mL^{-1}) than that of conventional LFIA. Electron microscopy (EM) is an essential tool for virus detection and transmission electron microscopy (TEM) is especially used to observe the virus particles in virus-infected plants. Amorphous inclusion bodies, formed by virus particles, can be observed in PVX-infected plant cells. *In situ* hybridization (ISH) technique detecting the mixed-infection of two PepMV isolates has been recently developed. Digoxigenin-labeled RNA probes, which targeted PepMoV genomic regions exhibiting a highly specificity and sensitivity for the two isolates, was used in the ISH technique.

Concluding Remarks

The complete genome sequences of AVX, YVX, and VVX have been determined recently. Novel potexviruses have been isolated from various plants. The genome of three definitive species, CsVX, LaMMoV, and PIVX, have not yet been completely sequenced. The phylogenetic relationship based on their genome sequences are not significantly associated with their natural host other than cactus-infecting viruses containing CVX, PiVX, OpVX, SchVX, and ZyVX. Some potexviruses have a putative ORF 6 within CP coding region or CP-3' NTR regions. Potexviruses are commonly known to be transmitted by aphids. Additionally, BaMV can be transmitted by diptera insects. *Rx* and *JAX1* genes regulate plant innate immunity against PVX. TGBp1 of PVX is a suppressor of RNA silencing that protects host cells against the pathogen. Potexviruses are currently mostly controlled by using virus-free seed production and early test of viral infection. Immunological and PCR-based techniques are most commonly used for detection of potexviruses.

Glossary

Pinwheel Characteristically shaped cylindrical inclusions present in the cytoplasm of cells infected by potyvirids.

PIPO (Pretty Interesting Potyviral ORF) Conserved ORF (Open Reading Frame) embedded within the genome of potyvirids in a frame different of the polyprotein, and expressed through polymerase slippage occurring in a conserved motif.

Polyprotein Protein, generally big in size, made of several smaller proteins. It is the gene expression strategy of potyvirids, as they are translated from large ORFs further processed by virus-encoded proteases.

Potyvirus Member of the family *Potyriviridae*.

Virion Viral particle.

Introduction

The existence of potyvirids as a specific group of plant pathogens with numerous members was recognized soon after the onset of virology as a scientific discipline. Historical evidence of symptoms caused by potyvirids in plants includes the color-breaking of infected tulip flowers that were reproduced in old Dutch paintings. Some members of this family were among the first plant viruses to be identified due to the importance of the diseases they cause, and it happened relatively soon after potyvirids were grouped according to common characteristics. Electron microscopy provided a clear taxonomic criterion to allocate viruses into the group by showing flexuous rod-shaped viral particles, and the consistent presence of pinwheel-shaped cytoplasmic inclusions in infected plant cells. Biological and serological studies, including vector organisms, genome composition and the deciphering of their full-length genome sequences, have contributed to taxonomically differentiate potyvirids into several genera. Currently, a still evolving classification recognizes at least ten genera and a few unclassified viruses.

The large number of viral species within the family *Potyriviridae* reveals its evolutionary success. More than 210 species are included in the family, with approximately 175 in the aphid-transmitted genus *Potyvirus*. Members of the family are distributed throughout the world, with each particular virus being geographically limited to the area potentially occupied by susceptible host plants. Generally speaking, host ranges are constrained to a limited number of natural and experimental hosts, although some potyvirids can infect a considerable number of plant species in many botanical families. Members of the family can infect economically important crops, including grain, legumes, forages, vegetables, fruits and ornamentals, causing severe losses and consequently fostering the interest of researchers, plant breeders and agronomists seeking practical solutions to the diseases that they cause.

The present entry focuses on current knowledge about viruses in the family *Potyriviridae*, dealing with taxonomy, evolution, diagnostics, molecular biology, functional and structural aspects of viral proteins, vector transmission and host-virus interactions, including characterization of resistance genes and defense responses, as well as biotechnological applications.

Taxonomy, Phylogeny and Evolution

Taxonomic standards for classification into the *Potyriviridae* family include: (i) properties of virus particles: long flexuous filaments (Figs. 1(a) and 2); (ii) cytopathological manifestations: presence of pinwheel or scroll-shaped cylindrical cytoplasmic inclusions in infected plant cells (Fig. 1(b)), and (iii) genome structure and expression strategy: positive sense ssRNA genomes, with 5' terminal proteins and 3' poly-A tails, translated as large polyprotein precursors, and at least one embedded out-of-frame ORF (see Fig. 4).

The family *Potyriviridae* is related to the picornavirus supergroup, having an equivalent main strategy for genome expression through polyprotein synthesis and further processing, and a well conserved set of replication-related proteins being present at equivalent positions in the different genomes, in particular a viral RNA-dependent RNA polymerase (RdRp).

Within the family, ten different genera are differentiated so far according to biological and molecular criteria. Potyviruses, for instance, are aphid-transmissible and possess a monopartite genome, characteristics that they share with macluraviruses, although particles of the latter are shorter in length and their first gene product in the polyprotein is missing. Other monopartite genera include whitefly-transmitted ipomoviruses, and eryophid mite-transmitted poacevirus, rymoviruses and tritoviruses, with vector organisms belonging to genera *Abacarus* and *Aceria*. The remaining genera (*Bevemovirus*, *Brambyvirus* and *Roymovirus*) include few species and, along with unclassified viruses, they still have no assigned vector. Bymoviruses, in turn, have bipartite genomes being encapsidated separately, and plasmodiophoraceous fungus-like organisms of the genus *Polymyxa* act as their transmission vectors. Phylogenetic analysis based on the alignment of genomic regions has established standard thresholds of around 50% and 75% of

Fig. 1 (a) Negative stain preparation of purified TEV particles. (b) Thin section showing the typical pinwheel shaped cytoplasmic inclusions present in cells of a *Nicotiana benthamiana* plant infected with PPV (bars equal 200 nm). Pictures are courtesy of D. López-Abella, CIB, CSIC.

nucleotide identities (variable depending on the considered segments) as demarcation criteria for assigning viruses to genera and species, respectively. The current classification is shown in [Table 1](#).

An example of phylogenetic analysis of potyvirus genomes is shown in [Fig. 3](#). All genera are differentiated in well-defined branches, with rymoviruses being close to potyviruses, although their distinctive biological characteristics justify their placement in different genera. Viral subgroups, particularly in members of the large genus *Potyvirus*, are also used for classification, following for instance host range restrictions as biological demarcation criteria. Information about taxonomy and sequence of members of the family *Potyviridae* is available at several web-based databases ([Table 2](#)).

Recombination, switching events, radiation, as well as host and geographical adaptation are proposed as drivers of evolution. Sub-populations able to differentiate and evolve independently within infected perennial plants illustrate the versatility and capacity of adaptation, and similar phenomena can happen in epidemics of viruses affecting annual hosts. Recombination of virus genomes can give rise to new virus entities with novel phenotypes in virulence, induction of symptoms, and even host range. Therefore, recombination events, partial duplications, indels and point mutations conferring different responses in infected host, as well as other factors, might help to explain the extraordinary variability observed among potyvirids.

Virion Structure

Virions of viruses belonging to the family *Potyviridae* are flexuous rods made by protein (95%) and RNA (5%) ([Figs. 1\(a\)](#) and [2](#)). They are about 11–15 nm wide, with lengths ranging from less than 700 nm, as in the case of macluraviruses, to up to 900 nm, as in ipomoviruses ([Table 1](#)). Available data on particle structure show a helical assembly of identical coat protein (CP) subunits

Fig. 2 Structure of potyvirus virions as determined at near-atomic resolution by cryoEM for WMV. (a) The diameter and pitch dimensions corresponding to the helical arrangement of 8.8 CP subunits per turn is shown in 3D density map (resolution 4.0 Å), with one of the subunit highlighted in blue. (b and c) The different parts are indicated according to the color code in the model and a cutaway section shows the inner side of the helix that forms a 70 Å channel. Images are courtesy of M. Valle, CIC bioGUNE, Spain. Reproduced from Zamora, M., Méndez-López, E., Agirrezabala, X., *et al.*, 2017. Potyvirus virion structure shows conserved protein fold and RNA binding site in ssRNA viruses. *Science Advances* 3. (eaao2182).

(about 2000) surrounding the nucleic acid, and a distribution of 8, 8 subunits per turn in the case of *Watermelon mosaic virus* (WMV).

Molecular weight of CP subunits ranges from 30 to 40 kDa, with differences mainly due to the variable length of the N-terminal region. A more conserved internal CP core (about 220 amino acids) defines particle architecture. The N-terminus appears to be surface-exposed, while the C-terminal part is located in the interior. Superficially located residues might interact with other proteins during essential processes of the virus life cycle. As an example, the conserved DAG motif near the N-terminus of the CP is required for aphid transmission. Posttranslational modifications, including phosphorylations and glycosylations, have been found in the CP of potyviruses, having potential regulatory functions during the viral cycle. Also, peculiar structures at one of the virion ends might represent the presence of VPg, HCpro and CI proteins, as observed in particles of purified Potato virus Y (PVY) and Potato virus A (PVA).

Properties of the Genome

The genome of monopartite potyvirids is an ssRNA molecule of + (messenger) sense. In all members, genomic RNA presents a 5' terminal protein (VPg) and a 3' poly-A tail of variable length. The genome size ranges from 8.2 to 11.5 kb, and it comprises an ORF that spans the whole genome and codes for a long polyprotein (340–370 kDa), which generates different mature products after ongoing an autoproteolytic processing cascade. An extra ORF, embedded in the P3 cistron and transcribed by viral RNA polymerase slippage events,

Table 1 Classification of virus species of the family *Potyviridae* into genera, with indication of type species, number of virus species, number of genomic RNAs, and taxonomically relevant characteristics like transmission vectors and particle morphology

Genus	Type species	Abbreviation	Number ^a	Genome	Particle ^b	Vector ^c
<i>Bevemovirus</i>	<i>Bellflower veinal mottle virus</i>	(BVMoV)	1	Monopartite	760 nm	Unknown

codes for the Pretty Interesting Potyviral QRF (PIPO) and generates the P3N-PIPO product. The bipartite genome of bymoviruses is divided into two RNAs: a long RNA-1 homologous to the 3' three-quarters portion of potyvirus monopartite genomes, and a short RNA-2 with partial similarity to the 5' region of the genome of other potyvirids. The proteolytic processing of the viral polyprotein depends on the action of either two (P1 and NIap_{ro}, or HCpro and NIap_{ro}) or three (P1, HCpro and NIap_{ro}) virus-encoded proteinases, depending on the species. In some cases, two divergent copies of P1 or HCpro could be part of the proteinase set of a single potyvirus. P1 serine- and HCpro cysteine-proteinases cleave in *cis* at their respective C-ends, whereas the NIap_{ro} serine-proteinase cleaves all the other sites, both in *cis* and *trans*. Information on processing cleavage sites for all known viruses of the family is available on a web-based database (Table 2). The dynamics of the proteolytic processes have been suggested to have regulatory implications for the sequential appearance and accumulation of intermediate and final products.

A typical potyvirus genome starts with a 5' non-coding region (NCR), with a variable length (less than 300 bp). This leader might act as a translational enhancer, and although the general mechanism is not fully understood, regulatory elements were found in this region. Studies in Plum pox virus (PPV), for instance, showed that (i) most of this region is dispensable for infectivity, although it contributes to viral competitiveness and pathogenesis, and (ii) translation takes place by a cap-independent leaky scanning mechanism. In the case of the 5'-leader of Tobacco etch virus (TEV), the existence of an internal initiation site has been suggested, with the presence of an RNA pseudoknot that provides cap-independent translation.

Another NCR variable in size (generally up to 200 bp) is located at the 3' end of the genome, just upstream of the poly-A tail. Putative RNA structures in this region confer pathogenic properties in Tobacco vein mottling virus (TVMV), and studies with TEV and Clover yellow vein virus (CIYVV) demonstrated the existence of *cis*-acting elements necessary for infectivity.

Properties and Functions of Gene Products Derived From the Polyprotein

The polyprotein encoded in the genome of most potyvirids comprises the following gene products (from N-terminus to C-terminus): P1, HCpro, P3 and P3N-PIPO (with PIPO in a different reading frame), 6K1, CI, 6K2, VPg, NIap_{ro}, NIb and CP. For bymoviruses, RNA-2 encodes two proteins P2-1 and P2-2, while RNA-1 encodes the remaining products starting with P3. Besides the information provided in Fig. 4, some characteristics of these products are given in this section.

The P1 protein is a serine protease, extremely variable in size (from 30 to 60 kDa), considered as an accessory factor for genome amplification. This region contains important sequence differences among potyvirids, and the whole cistron is even absent in macluraviruses and some unclassified potyvirids. In some ipomoviruses, such as Cucumber vein yellowing virus (CVYV), two P1-like serine proteinases are found in tandem, with the second one acting as a suppressor of gene silencing, likely compensating the absence of the HCpro cistron in its genome.

The helper component HCpro is a multifunctional protein named after its participation as a helper during aphid transmission. HCpro of tritimoviruses is also implicated in mite transmission. HCpro is smaller in macluraviruses, and sequences encoding a tandem of similar small HCpros are found in the genome of two potyvirids infecting areca palm, which has been proposed to become a novel genus tentatively named *Arepavirus*. A modular distribution of functions has been proposed for the HCpro of potyviruses: the N-terminus is essential for vector transmission, the central region is involved in suppression of RNA silencing, and the C-terminal part contains the papain-like cysteine protease activity. HCpro can interact with RNA, including double-stranded small interfering RNA molecules, a common feature of many other viral-derived RNA silencing suppressors. Structural studies with *Lettuce mosaic virus* (LMV) and TEV showed that HCpro form pairwise oligomeric structures. Relevant interactions of HCpro with several host factors have been described.

Fig. 3 Phylogenetic analysis derived from the comparison of full-length viral genome sequences of 38 members of the family *Potyviridae* belonging to different genera (a), and 122 members of the genus *Potyvirus* (b). Figures depict neighbour joining trees derived from Mega v6.06 after alignment by Muscle with 1000 bootstrap replicates, with branch lengths being proportional to genetic distance (substitutions per site). The bootstrap support (>0.7) for branches is indicated by proportional dots. For bymoviruses, the comparison was performed with a concatamer of RNA2 followed by RNA1. Viruses are identified by their official acronyms available at the ICTV webpage, and the sequences were obtained using the GenBank accession numbers of the corresponding type isolates, as found in the latest release (MSL34, from March 2019) of the Virus Metadata Repository (see Table 2). Grouping by genera and by number of genome segments are indicated as sectors in (a), where only the type member of potyviruses (PVY) is included, while the rest of selected members in the genus are shown in (b).

In the case of bymoviruses, very limited information is available about the role of P2-1 and P2-2. It has been postulated that P2-2 might participate in vector transmission, since non-transmissible variants exhibited deletions in this region. Intriguingly, sequence alignments indicate that P2-1, a putative cysteine proteinase, is indeed more closely related to HCpro than P2-2.

With the exception of P1 and HCpro, potyvirus gene products are excised from the viral polyprotein by the action of the NIpro proteinase. The third gene product is P3, a protein of unknown functions presumably implicated in RNA replication. An intrinsic difficulty to establish the actual role of P3 lays on the presence of the overlapping P3N-PIPO gene, which is directly involved in cell-to-cell movement. P3 is followed by the 6K1 peptide. Remarkably, separation of 6K1 from P3 in TEV does not occur *in vitro* and, moreover, this excision seems to be not required for the viability of PPV. Immunology studies determined the presence of both P3 and P3 + 6K1 in infected cells, and the latter is perhaps the functional product. Proteins encoded in the P3-6K1 region have been shown to play roles in host range definition and pathogenicity of several potyvirids.

The CI protein is the largest potyvirus gene product. It forms very distinctive pinwheel-shaped cylindrical inclusions in the cytoplasm of infected cells, with high taxonomic value because they are unique to members of the *Potyviridae* family (Fig. 1(b)). CI exhibits RNA helicase activity, and is supposed to act during RNA replication. Along with P3N-PIPO, CI forms conical structures at the cell plasmodesmata to allow viral cell-to-cell movement. 6K2 is a trans-membrane protein that induces the membrane remodeling needed for viral RNA replication and anchors the replication complex to virus-induced membrane structures. Studies with PVA 6K2 revealed that this protein might be also involved in movement and symptom induction.

The whole NIa (nuclear inclusion a) protein has about 49 kDa, but it is subjected to an internal suboptimal cleavage that gives rise to VPg (21 kDa), the protein covalently attached to the 5' end of viral RNA, and a proteinase fragment (NIpro, 28 kDa). VPg can be uridylylated *in vitro* by the RNA replicase NIb, suggesting that it is used as a primer during RNA replication, as in the case of picornaviruses. The VPg from diverse potyvirids, such as the one from Turnip mosaic virus (TuMV), can also counteract antiviral RNA silencing, a function involving direct interaction with, and promoting the degradation of, components of the host silencing machinery. In PVA, VPg is translocated as a 'phloem protein' that specifically acts in companion cells to facilitate virus unloading. ATPase activity was found in the VPg of Pepper vein banding virus (PVBV), being functionally autoinhibited by its N-terminal region, and stimulated by NIpro. The main role of NIpro is to act in *cis* and *trans* as the protease responsible for most cleavages in the polyprotein, processing sites mainly defined by specific heptapeptide sequences. NIpro shares structural motifs with host serine proteases, but it has a cysteine residue at the catalytic site. NIpro has non-specific RNA binding activity, and was shown to exhibit non-specific double-stranded DNA degradation activity in PVBV. The complete NIa can form inclusion bodies in the nucleus, where it is translocated responding to a bipartite nuclear localization signal. The crystal structure of TEV NIpro has been solved, providing clues on its mode of action.

NIb (nuclear inclusion b) is the RdRp responsible for viral replication. The recruitment of this protein towards the replication complex is postulated to occur via interaction with NIa. All NIb functions essential for RNA amplification can be provided in *trans*, as knockout TEV mutants lacking NIb infect transgenic plants expressing this protein. NIb is the second component of nuclear inclusions, being directed to the nucleus by specific signals in its sequence. Recent results with TuMV have shown that sumoylation of NIb occurs in the nucleus, and this modification retargets it to the cytoplasm where viral replication takes place. Moreover, sumoylation of NIb contributes to the suppression of the host NPR1-mediated immune response. Phosphorylation of TuMV NIb has been described, although it is still not known the significance of this post-translational modification.

The last product of the viral ORF is CP, a protein with many roles apart from coating and protecting the RNA genome. It is implicated in aphid transmission through interaction with HCpro, and in both cell-to-cell and long-distance movement. The importance of maintaining the net charge of the CP N-terminus for infectivity has been shown in TMV and Zucchini yellow mosaic virus (ZYMV).

Expression of Overlapping Gene Products

The presence of PIPO within the P3 cistron was predicted by bioinformatics analyses, including alignments of potyvirus genomes and synonymous sequence variability. This ORF is preceded by a conserved GA6 nucleotide sequence, a motif not present in other viral regions except in the case of a subgroup of sweet potato-infecting potyviruses, which harbor an additional GA6 within the P1 region that precedes a larger ORF named PISPO. Interestingly, the predicted P1N-PISPO gene product was found to be a suppressor of gene

silencing. Experimental evidence deriving from high-throughput sequencing of different potyvirus progenies support the idea that the changes in the reading frame required to produce these overlapping products occur during positive or negative strand (it is not yet defined) RNA synthesis by polymerase slippage. Interestingly, in another set of RNA species, an apparently equivalent mechanism causes the deletion of one nucleotide at the same GA6 motif in Clover yellow vein virus (CIYVV), with the consequent change in the reading frame. This deletion introduces a premature stop codon, and therefore a truncated P3, termed P3N-ALT, is produced. As P3N-PIPO, CIYVV P3N-ALT seems to participate in cell-to-cell movement.

Replication and Propagation

Potyvirus replicates in the cytoplasm of infected cells, as schematically shown in Fig. 5.

After entering the cell, the viral genomic RNA must be first translated in the cytoplasm. In general, the early events during infection are still poorly understood. Disassembly of particles might occur co-translationally, and after translation the replication complex must be formed with participation of several viral products and probably host factors. This complex uses the genomic RNA (+ sense) as template to generate a complementary chain (- sense) through a dsRNA intermediate, and proceed with the asymmetric synthesis of numerous molecules of genomic RNA. Viral-derived siRNAs have been shown to accumulate during potyvirus infections, revealing the action of host RNA silencing-mediated antiviral defenses. Therefore, potyviruses need to overcome this barrier, and for that they express RNA silencing suppressors. In the case of potyviruses, this role is mainly exerted by HCpro, although this function might be shared or displaced to other products in different genera. Studies performed with *Pea seed-borne mosaic virus* (PSbMV) served to identify a translation shut-off affecting many host proteins during infection. In the case of PVA, the shift for translation to replication appears to be controlled by phosphorylation-dependent RNA binding of non-assembled viral CP. The potyvirus expression strategy implies production of equimolar amounts of all gene products, giving rise to large excesses of some proteins, which might remain soluble, be degraded or secreted, or end up in inclusion bodies. It is intriguing that, whereas CI pinwheels are always formed, HCpro amorphous or NIa/NIb crystalline inclusions are present in some, but not all, viral infections.

Potyvirus RNA replication takes place in membranous vesicles derived from the endoplasmic reticulum that target chloroplasts and aggregate into large perinuclear globular structures. NIb forms the core of the replication machinery, with involvement of CI, VPg, 6K2, and NIaPro. Other factors, viral- and host-derived, might also be involved. For instance, the VPg of TuMV can interact with initiation factors eIF4E and eIF(iso)4E, and also with the Poly-A binding protein. The fact that several resistance genes, identified in host plants as potyvirus-specific, are related to translation initiation factors points to the importance of these interactions for the infection cycle.

Another critical process for a successful virus infection is the genomic RNA transport from the initially infected cell towards adjacent cells and distant tissues. In principle, the virus can invade the whole plant, with the probable exception of meristems, although a few seed-transmissible potyviruses might be capable of invading these particular tissues. The CP, but probably not virions, is essential for virus movement. RNA replication and virus movement appear to be closely linked. It has been proposed that replication vesicles are able to move through the cytoplasm along microfilaments to reach plasmodesmata and cross them in order to invade the neighboring uninfected cell, and that these vesicles are even able to traffic through the vascular system. In the process of local and systemic spread, host defenses must be confronted by the virus in a race to avoid its blockage by the action of both general and specific long-distance defensive signals.

The final step of the infective cycle is the virus spread to new plants, which rely on the acquisition of virions by the corresponding vector organisms and further transmission. Two viral proteins, CP and HCpro, are involved in the non-persistent aphid transmission of potyviruses. Available data supports a "bridge" hypothesis, in which HCpro serves as a reversible linker to retain virus particles in aphid mouthparts. A conserved PTK motif in the central portion of HCpro could participate in binding to the DAG motif at the N-terminus of CP, while a KTC domain at the N-terminal region of HCpro would be involved in binding to unknown structures on the aphid stylet. HCpro is also implicated in the semipersistent transmission of tritoviruses by eriophid mites. Less information is available about the transmission processes of macluraviruses by aphids, bymoviruses by plasmodiophorids, rymoviruses and poaceviruses by eriophid mites, and ipomoviruses by whiteflies.

Multifunctionality is observed in most potyviral proteins, illustrated for instance by HCpro. This capacity to participate in multiple processes suggests that potyvirus infection is not a consecutive succession of independent events, but a tightly regulated network of complex interactions, still to be elucidated, between viral and host factors.

Pathogenicity

The information about how potyviruses cause diseases in their host plants is very limited. Several studies have served to identify sequences and/or products in the genome of potyviruses directly implicated in the production of symptoms. As mentioned above, symptom determinants are even present in the 5'- and 3'-NCR. In addition, HCpro, P3, CI, 6K2 and VPg of different viruses have been described as determinants of pathogenicity, although single products were not always responsible for the different pathogenic responses.

As already mentioned, the P1/HCpro region was found to be responsible for the synergistic effect in mixed infections of potyviruses with unrelated viruses, perhaps reflecting the capacity of HCpro to counteract the RNA silencing-mediated defense. Interestingly, HCpro also interferes with the action of microRNAs, a particular type of regulatory host-derived small RNAs,

Fig. 4 Genome maps of representative viruses in the family *Potyviridae*. A monopartite virus characteristic of a potyvirus such as the type member of the genus PVY is shown in (a), together with SPFMV as representative of the sweet-potato infecting subgroup. Maps of representatives of other genera are shown for the macluravirus CdMV (b), three different ipomoviruses SPMMV, CVYV and CBSV (c), and the two genomic RNAs of the bipartite bymovirus BYMV (d). ssRNA genomes are shown as solid horizontal lines with VPg represented by solid circles at 5' end, and poly-A tails at 3' end. Viral ORFs are depicted as boxes divided in the different gene products, with their names indicated. The partially out-of-frame products deriving from polymerase slippage mechanisms are shown below. The protease-specific cleavages sites are indicated by arrows above the first map, with the matching symbol shown in the gene products responsible of the proteolytic process. Additional genome structures of other viruses (not shown) include the potyvirus EuRSV, containing a HAM1-like gene between Nib and CP coding sequences, and the still unclassified viruses of the proposed new genus *Arepavirus*, with presence of two HCPro-related cistrons, or the proposed new genus *Celavirus*, with a signal peptide preceding P1 and a very long 3' NCR.

providing a molecular explanation for some virus-induced symptoms. However, although it is tempting to regard interference with small RNAs metabolism in susceptible plants as a major element of pathogenicity, many other processes may also be affected. For example, specific features of the soybean *Rsv1*, a Soybean mosaic virus (SMV) resistance gene, appear to be responsible for the induction of either systemic mosaic or lethal systemic hypersensitive response in infected plants. The fact that the HCpro protein of LMV targets, and affects the functions of, the 26S proteasome might exemplify another way by which these viruses can cause disease symptoms. Despite the fact that in most cases the mechanisms of pathogenicity remain uncertain, it is reasonable to conclude that the final macroscopic effects of potyvirids are caused by a combination of additive interferences with several host functions and processes.

Fig. 5 Schematic representation of events during potyvirus infection of a plant cell. Colors of gene products match those displayed in Fig. 4. For simplicity, most organelles have been omitted, as well as the participation of host factors during the cycle. The accumulation of viral proteins as inclusions in different compartments is indicated. The cycle begins (left up) when the virus enters the cell, either from an adjacent infected cell or by inoculation from a vector organism. Then, the genomic RNA undergoes des-encapsidation, translation and processing to originate mature products. The replication complex involves participation of at least Nib, CI, VPg, 6K2, and Nla, together with host-derived factors, and uses the genomic RNA (+ sense) to generate a complementary chain (- sense), serving as template for the synthesis of numerous genomic RNAs. Also, during polymerization, variants with slippage at GA6 motifs could be generated and translated to yield partially out-of-frame products. dsRNA replicative intermediates or regions with secondary structure produce viral siRNAs by action of the host silencing machinery, which is counterattacked by suppressors of RNA silencing, such as HCpro or other viral products. After replication, the RNA progeny can move to adjacent cells through plasmodesmata, with involvement of P3N-PIPO, CI, VPg and CP, or it can be encapsidated and acquired to be transmitted again by a vector organism like aphids, in a process requiring HC-Pro. See text for further details.

Epidemiology and Control

Strategies currently applicable for the control of potyvirids are diverse, from cultural practices to the use of genetic resistance. Insecticide or other treatments against vectors are frequently considered unsatisfactory and have limited use because of the transmission type.

Severity of outbreaks is commonly related to abundance of initial foci of infection, dynamics of vector populations and other factors, such as the presence of weeds acting as reservoirs of viruses. The human intervention is responsible in many cases for the introduction of emerging diseases into new territories, while vector organisms are mainly involved in propagation within particular regions. For a few potyviruses, seed transmission is also an important means of dissemination. A typical example of well documented spread of a potyvirus over a territory and over time is the progressive emergence of Sharka disease, caused by PPV, in European countries during the XX century, and its recent diffusion to other continents to become nowadays a global pandemic.

The exploitation of pathogen-derived resistance and RNA silencing is yielding promising results for virus control. Transgenic plants incorporating viral sequences were found to be resistant to several potyvirids. An example of success is provided by the engineered papaya varieties, which are resistant to *Papaya ringspot virus* due to the expression of the cognate viral CP as a transgene. Nowadays, RNA silencing is being further exploited for resistance by designing specific transgenes with hairpin structures as sources of viral-derived siRNAs, or even by direct application of dsRNAs. Other approaches to achieve resistance include the expression of ribozymes, plantibodies or proteinase inhibitors. Cross-protection has also been related to RNA silencing mechanisms, although other processes could be operating, as suggested by the involvement of specific proteins, such as NIap and CP, in superinfection exclusion. Stability, durability and biosafety issues of the different strategies are under constant evaluation.

The identification of potyvirus-specific resistance genes in host plant is also leading to important advances. These studies indicate that canonical resistance genes might be operating, for instance TIR-NBS-LRR class in PVY, or NBS-LRR class in SMV. Other examples of dominant resistance genes acting against different potyviruses are the three *Restricted TEV Movement (RTM)* genes, which code for a jacalin-type protein, a small heat shock protein and a MATH domain-containing protein. As mentioned, mutations in eukaryotic initiation factors are frequently found as responsible for recessive resistance against potyvirids, but particular features of other host factors, as the products of *PROTEIN DISULFIDE ISOMERASE LIKE 5-1* of barley or two MATH domain-containing genes of apricot, has been also found to be associated with natural recessive resistance against potyvirids. Therefore, the generation of variability in candidate genes, using TILLING or equivalent platforms, must be a promising strategy for the generation of resistant plants.

Diagnosis

Serological tools have been the preferred diagnostic system for potyvirids. While the non-structural viral proteins have limited use in serological diagnosis, the virus particles are in general strongly immunogenic. However, serological relationships among potyvirids are complex, with unexpected and inconsistent cross-reactivities hindering their application in taxonomy and specific virus identification. The cause of this phenomenon is the presence of common epitopes in the conserved internal CP core, while specific epitopes map in the variable N-terminus, a surface-exposed region prone to degradation. New species-specific antibodies targeting the immunodominant N-terminal region of CP provide excellent tools for the serological detection of many potyvirids.

RT-PCR is another way to deal with diagnosis. Degenerated primers matching conserved genomic regions might allow the amplification of virtually any potyvirus. For instance, primers flanking the variable CP N-terminal region have been developed and successfully used for both detection and identification of highly divergent potyvirids. Interestingly, the combination of serological capture of virions followed by highly sensitive RT-PCR has resulted in robust detection systems. Together, these molecular tools have been extensively used to identify new viruses infecting new hosts. The application of new technologies and modern molecular methodologies to diagnostics is being continually updated, which results in more sensitive and more specific approaches.

Concluding Remarks

The abundant information on potyvirids have reached a level that allows to develop biotechnological applications, including the production of foreign proteins in plants using virus-based expression vectors, and also the exploration of viruses as direct sources of genetic elements and functionally active products, such as the NIap proteases used to remove affinity tags from fusion proteins. Another example is the use of HCpro to block the host RNA silencing machinery with the consequent boost in the expression of products in plants.

Several potyvirids have been engineered and tested as expression vectors. Small peptides can be expressed as CP-fusion products, allowing the protein chimeras to be used as antigen presentation systems for immunization or diagnosis. Complete foreign genes have been expressed in vectors based on a quite large list of potyvirids, which covers an important range of potential hosts. The seminal work with TEV pointed to the P1/HCpro junction as an adequate insertion site for foreign sequences, but additional sites were exploited later, such as the NIb/CP junction or the P1 region. Moreover, more recent reports demonstrated the huge versatility of potyvirids for the expression of foreign genes, as they can even express different products simultaneously from independent insertion sites.

To summarize, it can be concluded that the family *Potyriviridae* is a fascinating group of viruses. Keeping key genomic features, potyvirids have diverged in a multitude of lineages, which we have yet to finish to discover, and one of them, the genus *Potyvirus*, can be considered one of the most successful in the world of viruses. The currently available knowledge about potyvirus replication, movement and transmission is allowing the development of new control strategies aiming to interfere with key-steps in the virus life cycle. Structure resolution of viral components might also serve to explore new resistance strategies. Diagnostic tools are continually under improvement, and future developments will certainly supply specific and sensitive means of virus identification. Our current insight about the selective participation of different host factors in resistance and pathogenesis is fueling works aiming to understand the complex virus-plant crosstalk that occurs during the infection. Besides, peculiarities of certain viruses are being unraveled, and these findings will help to discover new generic features and specificities of members of the *Potyriviridae* family. All in all, the study of potyvirus infections at the molecular level has been extraordinarily successful over the last years, and is likely to continue providing relevant data on the viruses, as well as in terms of understanding many plant processes.

Nomenclature

aa Amino acid(s)
AlkB Alpha-ketoglutarate-dependent dioxygenase
CP Coat protein or capsid protein
CRP Cysteine-rich protein
cSSR Compound simple sequence repeat
Hel Helicase
kb Kilobase
kDa Kilo dalton
LAMP Loop mediated amplification
MP Movement protein
NLS Nuclear localization signal
nt Nucleotide(s)
NTR Non-translated region

ORF Open Reading Frame
PCR Polymerase chain reaction
Pol RNA-dependent RNA polymerase
Poly(A) Polyadenylated
P-Pro Papain-like protease
RdRp RNA-dependent RNA polymerase
RT-PCR Reverse transcription polymerase chain reaction
S_{20,w} Corrected sedimentation coefficient; extrapolated in water at 20°C and infinitely diluted
SSR Simple sequence repeats
ssRNA Single-stranded RNA
TGB Triple gene block
ZF Zinc finger motif

Glossary

AlkB protein The protein found in bacteria, fungi, and mammalian genomes is iron (II)- and 2-oxoglutarate-dependent dioxygenases that remove alkyl adducts from oxidative dealkylation DNA repair reverse methylation damage, such as 1-methyl-adenine and 3-methyl-cytosine. Viral AlkB proteins can repair alkylated bases in DNA or RNA.

Cysteine-rich protein The protein related to viral pathogenicity determinants. The CRPs can be divided into two groups according to their domain structures. The CRPs with a conserved CGxxH motif (C, cysteine; G, glycine;

H, histidine; x, any aa residue). The CRPs with an arginine-rich nuclear localization signal (NLS) in the central part of the protein. Carlavirus CRPs contain a zinc finger motif (ZF) located adjacent to the NLS.

RNA silencing suppressor Plant viruses are encoding proteins to counteract the plant antiviral system known as RNA silencing.

Triple gene block The protein consists of a strikingly similar element of three partially overlapping ORFs and is included in their genomes. The TGB proteins are related to cell-to-cell movement and potentially influence on host antiviral defenses.

Introduction

The subfamily *Quinvirinae*, family *Betaflexiviridae*, contains three genera (*Carlavirus*, *Foveavirus*, and *Robigovirus*) and three unassigned species. The complete genome sequences of most of the members of the subfamily *Quinvirinae* have been determined recently. The members of the genus *Carlavirus* contain 58 species including *Carnation latent virus* (CLV) as the type species for the genus *Carlavirus*. The members of the genus *Foveavirus* contain 8 species including *Apple stem pitting virus* (APSV) as the type species for the genus *Foveavirus*. The members of the genus *Robigovirus* contain 5 species including *Cherry necrotic rusty mottle virus* (CNRMV) as the type species for the genus *Robigovirus*. The genus *Robigovirus* has been recently established as a new member of the subfamily *Quinvirinae* by the International Committee on Taxonomy of Viruses (ICTV). The members of the subfamily *Quinvirinae* can be divided into two or three main phylogenetic groups based on their genome sequences. The two genera, *Foveavirus* and *Robigovirus*, and unassigned species can be clustered in one branch. The phylogenetic relationships of the subfamily *Quinvirinae* are not associated with their natural host. The virions of the subfamily *Quinvirinae* have non-enveloped and flexible filaments of 640–1000 nm in length and 12–15 nm in diameter. Their genomes are composed of a positive-sense single-stranded RNA (ssRNA) with 5' terminal cap structure and a 3' terminal poly(A) tail, and contain RNA-dependent RNA polymerase (RdRp) for viral replication, triple gene block (TGBp1, 2, and 3) for viral movement (MP), and coat protein (CP). The RdRp contains five conserved protein domains as follows: an AlkB domain; a papain-like protease (p-Pro) domain; an RNA helicase (HEL) domain; a polymerase (POL) domain. The sizes of the genomes have 7.4–9.3 kbp. The genomes of the carlaviruses contain mostly a cysteine-rich protein (CRP) including a nuclear localization signal (NLS) and a zinc finger motif (ZF). Most viruses have a relatively restricted host range, which may exhibit mosaic, mottle, ringspot, necrosis, or pitting symptoms or may be symptomless. Most viruses are spread by mechanical transmission and some viruses can be transmitted by insect vectors, such as aphid and whitefly. Some viruses are often transmitted by seed and grafting. Virus diseases caused by some viruses can seriously damage major crops and the viruses require suitable disease managements.

Taxonomy and Phylogeny

Three genera, *Carlavirus*, *Foveavirus*, and *Robigovirus*, are members of the subfamily *Quinvirinae* within family *Betaflexiviridae*. The genus *Carlavirus* contains 53 definitive species, of which 41 are determined completed genome sequences (Table 1). Its name is derived from *Carnation latent virus* (CLV, the type species of *Carlavirus*). The CLV genome has not been completely sequenced. The genus *Foveavirus* contains 8 definitive species, these viruses have complete genome sequences (see Table 1). Its name is derived from Latin *fovea* for “pit” or “hole”, which is a type of symptom induced by the type species (Apple stem pitting virus, ASPV). The genus *Robigovirus*, a newly created genus within the subfamily *Quinvirinae*, contains 5 definitive species, these viruses have complete genome sequences (Table 1). Its name is derived from Latin *robigo* for “rust”, which is a type of symptoms induced by the type species (Cherry necrotic rusty mottle virus, CNRMV). Additionally, the subfamily *Quinvirinae* contains three unassigned species *Banana mild mosaic virus* (BanMMV), *Banana virus X* (BanVX), and *Sugarcane striate mosaic-associated virus* (SCSMaV). Phylogenetic tree of members of the subfamily *Quinvirinae* has revealed a clustering into two major groups of their RNA-dependent RNA polymerase (RdRp) aa sequences (Fig. 1(A)). The major group I consists of members of the genus *Carlavirus* whereas the major group II can be divided into three distinct subgroups (carlavirus, foveavirus, and robigovirus groups). The carlavirus group within the major group II contains Sweet potato chlorotic fleck virus (SPCFV), Melon yellowing-associated virus (MYaV), and Nerine latent virus (NeLV). The foveavirus group has divided into three branches and ASPV, the type species of *Foveavirus*, is closely grouped with Apricot latent virus (ApLV). The two unassigned species, BanMMV and SCSMaV, are supported as members of the robigovirus group within the major group II. The robigovirus group is divided into two branches and CNRMV, the type species of *Robigovirus*, is more closely related to Cherry twisted leaf associated virus (CTLAV). In the phylogenetic tree of the coat protein (CP), *Foveavirus*, *Robigovirus*, and unassigned species are clustered in one branch (Fig. 1(B)). The foveavirus group could be divided into three branches and the ASPV is more closely grouped with Apple green crinkle associated virus (AGCaV) than the ApLV. The robigovirus group is divided into two branches and the CNRMV is more closely grouped to Cherry rusty mottle associated virus (CRMAV) than the CTLAV. Of three sambucus-infecting viruses in the phylogenetic trees of the RdRp and CP, *Sambucus virus C* and *Sambucus virus E* that are grouped together are more closely related than *Sambucus virus D*. Four cherry-infecting robigoviruses in the phylogenetic trees, Cherry green ring mottle virus (CGRMV), CNRMV, CTLAV, and CRMAV, are clustered in one branch. The aa sequence identities of their RdRp and CP proteins of the subfamily *Quinvirinae* are less than 67.6% and 85.5%.

The phylogenetic trees of the TGBp1, TGBp2, and TGBp3 of the subfamily *Quinvirinae* could be divided into three major groups (Fig. 2). The two genera, *Foveavirus* and *Robigovirus*, and unassigned species in the phylogenetic tree of the TGBp1 are clustered in one branch, similar to those of the RdRp and CP. The two genera in the TGBp2 and TGBp3 are clustered in distinct branches. In the tree of the TGBp3, the members of the genus *Foveavirus* are clustered in distinct branches. Two foveaviruses, Grapevine rupestris stem pitting-associated virus (GRSPaV) and Grapevine virus T (GVT), clustered together are more closely related to three carlaviruses, Potato latent virus (PotLV), Hippeastrum latent virus (HLV), and Cowpea mild mottle virus (CPMMV), than to other foveaviruses. The cheery-infecting viruses except for CGRMV, which is missing the TGB aa sequences, are clustered in one branch. The aa sequence identities of their TGBp1, TGBp2, and TGBp3 proteins of the subfamily *Quinvirinae* are less than 72.2%, 79.0%, and 63.9%, respectively. Phylogenetic tree based on a cysteine-rich protein (CRP) aa sequences of members of the genus *Carlavirus* is revealed that divided into five groups. Of three sambucus-infecting viruses, SVC and SVE are grouped together, whereas SVD is grouped with Pea streak virus (PSV) in a distinct branch. The aa sequence identities of their CRP proteins is less than 77.1%.

Virion Structure

Virions are non-enveloped and flexible filaments of 640–1000 nm in length and 12–15 nm in diameter. Carlavirus and foveavirus particles are 610–700 nm and 800–1000 nm in length, respectively. Carlaviruses have helical symmetry with a pitch of 3.4–3.6 nm. Carlaviruses virion Mr is about 60×10^6 with 5.4%–6% nucleic acid content. Carlaviruses have the sedimentation coefficient ($S_{20, w}$) of 147–176S, the buoyant density in CsCl of 1.3 g cm^{-3} . Potato virus M (PVM), Shallot latent virus (SLV), and Daphne virus S (DVS) have the sedimentation coefficient ($S_{20, w}$) of 157S, 147.5S, and 174 S, respectively. A carlavirus isolated from elderberry (*Sambucus* spp.) has the sedimentation coefficient ($S_{20, w}$) of 155S and molecular weight of CP subunits of 31 kDa. The virus is an average normal length of 678 nm in length and 12 nm in diameter. The virus particles can be observed in the cytoplasm of their infected plant. The virus particles of *Helloborus net necrosis virus* (HeNNV) is approximately 800 nm in length and 17 nm in diameter. The virions of ASPV, Grapevine rupestris stem pitting-associated virus (GRSPaV), and CGRMV apparently do not contain lipids or carbohydrates.

Genome Organization

The genome is a positive-sense single-stranded RNA (ssRNA) with 5' terminal cap structure and a 3' terminal poly(A) tail. The genome is 7.4–9.3 kb in size and contains five or more ORFs. ORF1 encodes a large polypeptide that is RdRp including domains of methyl-transferase, helicase, and polymerase. ORFs 2, 3, and 4 constitute the TGB that facilitate virus movement. ORF5 encodes the CP and ORF6 encodes a cysteine-rich protein (CRP). The genome structures of the distinguished genera in the subfamily *Quinvirinae* is showed in Fig. 3. The genome of PVM, a member of the genus *Carlavirus*, consists of 8533 nt and contains six ORFs

Table 1 Virus species of three genera (*Carlavirus*, *Foveavirus*, and *Robigovirus*) of the subfamily *Quinivirinae*, family *Betaflexiviridae*. Type species in the genera are written in bold. Complete sequences of the genomes are indicated

Genus/Virus name	FYI	Particle size (nm)	Natural Hosts	Symptoms	Transmission	Distribution	Access #

Fig. 1 Phylogenetic analysis of subfamily *Quinvirinae* based on the amino acid sequences of the RdRp (A) and CP (B). Multiple sequence alignments were generated using DNAMAN software version 5.1 (Lynnon Biosoft, San Ramon, CA, USA) and phylogenetic trees were constructed by the neighbor-joining algorithm, based on calculations from pairwise amino acid sequence distances for protein analyses derived from the multiple alignment format. The horizontal branch lengths are proportional to the genetic distance, and the numbers at each point indicate bootstrap values. The dataset was subjected to 10,000 bootstrap replicates. Square brackets denote accession numbers in the NCBI database.

coding for proteins of 223 kDa RdRp (5907 nt), 25 kDa TGBp1 (690 nt), 12 kDa TGBp2 (330 nt), 7 kDa TGBp3 (192 nt), 34 kDa CP (915 nt), and 11 kDa CRP (327 nt) from the 5' to 3'-end. The both terminal regions of TGBp2 (12 kDa) shows overlap with TGBp1 and TGBp3, respectively. The 5'-terminal region of ORF6 shows an overlap with ORF5 (CP). The lengths of the 5' non-translated region (NTR) and the 3'-NTR have 73 and 72 nt. The 3'-NTR region contains the poly (A) tail. The genome of ASPV, a member of the genus *Foveavirus*, consists of 9332 nt and contains five ORFs encoding 247 kDa RdRp (6552 nt), 25 kDa TGBp1 (672 nt), 13 kDa TGBp2 (363 nt), 7 kDa TGBp3 (213 nt), and 44 kDa CP (1245 nt) from the 5' to 3'-end. The 3'-terminal region of TGBp2 shows an overlap with TGBp3. The lengths of the 5'-NTR and the 3'-NTR have 59 and 133 nt. The 3'-NTR region contains the poly(A) tail. The genome of CNRMV, a member of the genus *Robigovirus*, has 8432 nt and contains five ORFs encoding 232 kDa RdRp (6117 nt), 25 kDa TGBp1 (669 nt), 12 kDa TGBp2 (348 nt), 7 kDa TGBp3 (204 nt), and 30 kDa CP (804 nt) from

Fig. 2 Phylogenetic analysis of subfamily *Quinivirinae* based on the amino acid sequences of the TGBp1 (A), TGBp2 (B), and TGBp3 (C). Green and yellow boxes indicate respectively members of the genus *Foveavirus* and members of the genus *Robigovirus*. Multiple sequence alignments were generated using DNAMAN software version 5.1 (Lynnon Biosoft, San Ramon, CA, USA) and phylogenetic trees were constructed by the neighbor-joining algorithm, based on calculations from pairwise amino acid sequence distances for protein analyses derived from the multiple alignment format. The horizontal branch lengths are proportional to the genetic distance, and the numbers at each point indicate bootstrap values. The dataset was subjected to 10,000 bootstrap replicates. Square brackets denote accession numbers in the NCBI database.

the 5' to 3'-end. The 3'-terminal region of TGBp2 shows an overlap with TGBp3. The genome has putative 13 kDa and 18 kDa within the TGBp1 and the CP, respectively. The lengths of the 5'-NTR and the 3'-NTR have 117 and 192 nt. The 3'-NTR region contains the poly(A) tail.

Properties and Functions of Gene Products

The RdRp of quiniviruses contains five conserved domains: a methyl-transferase (MT) domain; an AlkB domain; a papain-like protease (*p*-Pro) domain; a RNA helicase (HEL) domain; a polymerase (POL) domain. The AlkB domain that repairs alkylated RNA is located in the RdRp of quiniviruses, potexviruses, and potyviruses. The papain-like protease (*p*-Pro) is related to polyprotein processing in viral replication. TGB resembling potex-like TGB that is essential for their cell-to-cell and long-distance movement.

Fig. 3 Comparison of the genome organizations of the different genera (*Carlavirus*, *Foveavirus*, *Robigovirus*) in the subfamily *Quinvirinae*. RNA-dependent RNA polymerase (RdRp) includes a methyl-transferase (MT), an AlkB domain, a papain-like protease (P-Pro) domain, a helicase (HEL) domain, and a polymerase (POL) domain. Gray box indicates triple gene block corresponding to three overlapping ORFs (TGBp1, TGBp2, and TGBp3). ORF5 encodes coat protein (CP). The ORF6 of PVM, genus *Carlavirus*, encodes a cysteine-rich protein (CRP).

TGBp1 is associated with ATPase, RNA-binding, and RNA-helicase activities. TGBp2 and TGBp3 are integral membrane proteins required for virus movement. The TGBp1 and CP form a complex with viral RNA that transfers via the plasmodesmata. TGBp1 acts as viral suppressors of RNA silencing. The TGBp1 of PVM demonstrates suppressor activity on systemic silencing. The CP is required for virion assembly. The CRP (ORF6) of carlaviruses contains two motifs: a nuclear localization signal (NLS) and a zinc finger motif (ZF). The CRP is implicated as silencing suppressors for a pathogenicity determinant. The CRPs of PVM, DVS, Chrysanthemum virus B (CVB), Lily symptomless virus (LSV), HeNNV, and Narcissus common latent virus (NLV) have the ability to enhance the pathogenicity of a heterologous virus (Potato virus X) and effects on virus accumulation levels. The CRPs of genera *Benyvirus*, *Tobravirus*, *Furovirus*, and *Hordeiviruses* have a similar role to that of the carlavirus CRP. The analysis of simple sequence repeats (SSRs) and compound simple sequence repeat (cSSR) have been demonstrated in 32 species of carlaviruses. Mononucleotide A/T is most commonly followed by dinucleotide GT/TG and trinucleotide AAG/GAA in their genome. The SSR and cSSR are mainly located in the RdRp and CRP independent of their genome size.

Replication and Propagation

ORF1 (RdRp) is translated directed from the genomic RNA. The ORF1 of Blueberry scorch virus (BlScV), a member of the *Carlavirus* genus, is proteolytically processed by a papain-like proteinase. The largest product of 190 kDa can be synthesized *in vitro* using the viral RNA of Potato virus S (PVS) isolated from infected potato plant. The proteolytic processing of the 190 kDa protein is associated with accumulation of 150 kDa peptide after 60 min incubation. L-canavanine is related to specifically reduce the quantity of 34 kDa for PVS CP. *Carlavirus* ORF1 and TGBp3 contain a heptanucleotide motif (C/UUUUAGGU) for sub-genomic RNA promoter. Two sub-genomic RNAs for TGB, CP, and CRP synthesis have been demonstrated in some carlaviruses. These sub-genomic RNAs might be encapsidated into their viral particles. Virus particles are usually found in the cytoplasm in infected plant.

Transmission and Host Range

Most carlaviruses are spread by mechanical transmission in horticultural crops and herbaceous plants. Some carlaviruses, American hop latent virus (AHLV), BlScV, DVS, LSV, Hop latent virus (HPLV), Hop mosaic virus (HpmV), Potato virus S (PVS), PVM, and PotLV, can be transmitted non-persistently by aphid. AHLV, HPLV, and HpmV are known to infect to hop plants and known to occur in mixed infection. The three viruses are transmitted by hop aphid (*Phorodon humuli*). HPLV and HpmV are

transmitted by potato aphid (*Macrosiphum euphorbiae*) and green peach aphid (*Myzus persicae*), and can also be transmitted by mechanical inoculation. AHLV and HpLV cause commonly symptomless on any commercial hop plants. HpMV causes chlorotic mosaic mottling on susceptible hop plants. BLSv can cause necrosis of flower and young leaves, shoot blight, and chlorosis in highbush blueberry (*Vaccinium corymbosum* L.) whereas it appears to be asymptomatic in cranberry (*Vaccinium macrocarpon* L.). PVS is mechanically transmissible and causes severe disease in potato and localized infection of *Chenopodium* spp. The virus recently has been detected from arracacha (*Arracacia xanthorrhiza*) in Peru. Two purified carlaviruses, Pea streak virus and Red clover vein mosaic virus (RCVMV) causing severe streaking symptoms on pea, can be transmitted by *Acyrthosiphon pisum* (pea aphid). The RCVMV can be mechanically transmitted to chickpea (*Cicer arietinum* L.), faba bean (*Vicia faba* L.) and lentil (*Lens culinaris* Medik.). Ligustrum necrotic ringspot virus (LNRSV) isolated from *Ligustrum japonicum* Thunb showing necrotic ringspots and line patterns is mechanically transmissible to *Chenopodium amaranticolor*. CPMV is transmitted non-persistently by whitefly and is the possibility of seed transmission. The virus can cause systemic mottling, chlorotic blotches, and leaf malformations in cowpea (*Vigna unguiculata* L.) and can be naturally transmitted to peanut (*Arachis hypogaea* L.), soybean (*Glycine max* L.), and common bean (*Phaseolus vulgaris* L.). Cucumber vein-clearing virus (CuVCV) can be transmitted by mechanical inoculation and by whitefly. Melon yellowing-associated virus also is transmitted by whitefly but is not transmitted by mechanical inoculation. Rose virus A has been detected recently in a memorial rose (*Rosa wichuraiana* Cresp.) showing leaf deformation and mosaic symptoms. Foveaviruses and robogoviruses naturally infect woody plants (Fig. 5). These viruses can be transmitted by grafting and sap inoculation. ASPV causes systemic infection on *Nicotiana occidentalis* and local infection on *Chenopodium murale*. ApLV, a member of the genus *Foveavirus*, causes chlorotic spots on *Prunus persica* and *P. cerasifera*, red to purple rings and mottling on *P. avium*, and chlorotic blotching and malformation on *P. armeniaca* cv. Tirynthos and Haward but not on flowers and fruits. The ApLV can cause asymptomatic infection on cherry and plum cultivars. CGRMV can be sap transmitted from cherry to cherry. Novel foveavirus has been detected in stems and leaves of ginseng (*Panax ginseng*) exhibiting mosaic and ringspot symptoms. GRSPaV can be transmitted by grafting but not

transmitted by mechanical inoculation. The five members of the genus *Robigovirus* can be transmitted to cherry and other stone fruit tree and cause serious diseases (Figs. 4 and 5; Table 1).

Epidemiology and Control

Quinviruses can cause usually mosaic, mottle, and ringspot symptoms in their host plants. PVS and PVM, members of the genus *Carlavirus*, are essentially symptomless in most potato cultivars. The two viruses are easily transmitted during the cutting of tubers to make seed pieces. The PVS can cause yield losses of up to 20% in potato field. The primary method for producing virus-free potato tuber seeds has been used to control the viruses. The *Ns* gene derived from potato (*Solanum tuberosum* spp. *andigena*) induces hypersensitive resistance to PVS and have been used in potato breeding programs. Orchards and vegetables sustain economic damage caused by some quinviruses that require suitable disease management. MYaV, a member of the genus *Carlavirus*, causes severe yellowing disease in melon crops and could transmitted by whitefly. New melon plants containing a dominant MYaV resistance gene recently have been developed for the virus disease management. A whitefly-transmitted CPMMV, a member of the genus *Carlavirus*, causes substantial losses in the yield and quality of cowpea. The whitefly-transmitted CPMMV can be controlled with insecticides such as Nuprid 2F and Dimethoate. The SSR markers associated with CPMMV resistance in cowpea have been recently identified and will be used for new cowpea variety resistance to CPMMV. HeNNV, a member of the genus *Carlavirus*, associated with black death of *Helleborus* spp. has been reported in New Zealand, Japan, UK, and the USA. LSV, a member of the genus *Carlavirus*, which is generally symptomless in field-grown plants may cause problems under the insufficient light and

growing conditions of year-round cut-flower production in greenhouses. In the Netherlands, an aphid-transmitted LSV spreads mainly in June–July, considerably less in May, and least in August/September. It is curtailed by a mixture of mineral oil and pyrethroid insecticide. Three hop viruses, AHpLV, HpLV, and HpMV, can be controlled by the use of certified virus-free planting stock and insecticides for reducing aphids. HpMV has been found infecting hops in Europe, Australia, the United States, New Zealand, China, Japan, and South Africa. Blueberry scorch disease caused by aphid-transmitted BLSV is a severe disease of highbush blueberry (*Vaccinium corymbosum* L.) in Canada, Europe, and the USA. The viral disease can be controlled by heat therapy and apical meristem culture. Transgenic chrysanthemum, tobacco, and potato, which are resistant to CPMMV, Chrysanthemum virus B, PVM, and PVS have been developed.

Diagnosis

Quinviruses can be detected by polymerase chain reaction (PCR)-based methods, such as reverse transcription (RT)-PCR, immunocapture-RT-PCR, multiplex RT-PCR, and real-time PCR. Universal primers for detection of potato carlaviruses (PVS, PVM, and PotLV) have been developed based on the conserved aa sequences “SNNMA” and “GLGVPTE” in the CP. Other universal primer, a Carla-CP, has been designed based on the conserved nt sequences of the GLGVPTE motif in the CPs derived from 17 carlavirus species (Aconitum latent virus, BLSV, Carnation latent virus, Cole latent virus, CPMMV, CVB, DVS, Helenium virus S, HpMV, LSV, Narcissus common latent virus, Passiflora latent virus, PotLV, PVM, Potato virus P, PVS). Carlaviruses can be detected by RT-PCR using the Carla-CP and oligo-d(T21) primers. Some commercial and non-commercial antisera are used for immunological detection of quinviruses. Four carlaviruses, CLV, HpLV, HpMV, and PVS are antigenically similar.

Concluding Remarks

Two genera, *Carlavirus* and *Foveavirus*, belong to subfamily *Quinvirinae* and a newly created genus *Robigovirus* has been recently added to that subfamily. The completed genome sequences of novel carlaviruses (LAV, MYaV, and SPCFV) and foveavirus (GVT) have been determined recently. African oil palm ringspot virus, Cherry green ring mottle virus, CNRMV, Cherry rusty mottle associated virus, and Cherry twisted leaf associated virus belong to newly established genus *Robigovirus*. In phylogenetic trees based on their RdRp and CP proteins of members of the subfamily *Quinvirinae*, the genera *Carlavirus* and *Foveavirus* have not been grouped according to their natural host species. Cowpea, cherry, grapevine, melon, and potato cause severe symptoms by some quinviruses. Some carlaviruses can be transmitted by aphid and whitefly. Quinviruses have TGB resembling potex-like TGB for viral movement. Carlaviruses have two proteins (TGBp1 and CRP) identified as RNA silencing suppressor. Immunological and PCR-based techniques are most commonly used for detection of quinviruses.

Glossary

Chromoviruses In reference to metaviruses coding for chrodomain-like integrases.

Errantivirus Erranti comes from the Latin errans, meaning to wander.

LTR-retroelement Term used to collectively refer to retroviruses and LTR-retrotransposons, regardless of whether they possess env or env-like proteins.

Metavirus Meta comes from the Greek metathesis for transposition.

Monophyletic Phylogenetic group collecting the full set of operational taxonomic units descending from a single ancestor.

Operational taxonomic unit Termed used to classify groups of closely related individuals.

Ortervirales Orter is an inversion of retro, which was derived from reverse transcription; and virales - which is the suffix for an order in virology.

Paraphyletic clade Phylogenetic group collecting some but not all operational taxonomic units descending from a single ancestor.

Polyphyletic Phylogenetic group composed of OTUs descending from more than one ancestor.

Pro-retroviruses Term used here to describe LTR retrotransposons that have acquired a third ORF, *env*, and are thus potential retrovirus but with no evidence of infectivity.

Pseudovirus Pseudo comes from Greek pseudo, “false” to connote some uncertainty as to whether these are true viruses.

Semotivirus Semoti comes from the Latin semotus, meaning distant or removed (it was formerly used to classify Belpao elements).

Introduction: The Paradigm of LTR Retrotransposons and Reverse-Transcribing Viruses

Metaviridae, *Pseudoviridae*, and *Belpaoviridae* are the three families officially introduced by the International Committee on Taxonomy of Viruses (ICTV) for classification of the eukaryotic Ty3/Gypsy, Ty1/Copia, and Bel/Pao LTR retroelements. The members of the families *Metaviridae*, *Pseudoviridae*, and *Belpaoviridae* are widely (but differentially) distributed in plants, fungi and animals where they may exist as LTR retrotransposons or as potential or true reverse-transcribing viruses. Due to multiple distinct similarities in the life cycles, sequence and architecture of genes, and functional features, it is commonly accepted that members of the families *Metaviridae*, *Pseudoviridae*, and *Belpaoviridae* share origins and evolutionary history with viruses of the *Retroviridae* family, which is thus considered as a member of the same phylogenetic lineage of reverse-transcribing viruses and LTR retrotransposons. It is worth for the reader to distinguish simple reverse-transcribing viruses from the complex ones. In the family *Retroviridae*, simple retroviruses are those that present a core genomic organization of *gag*, *pol*, and *env* genes flanked by LTRs, with no accessory genes (i.e., LTR-*gag-pol-env*-LTR), while complex retroviruses incorporate one or more accessory genes (*vif*, *vpx*, *rev*, *nef*, *tat*, or others) needed to complete the life cycle and infect other cells (Fig. 1). In their most current form, the members of the families *Metaviridae*, *Pseudoviridae*, and *Belpaoviridae* are LTR retrotransposons presenting a “LTR-*gag-pol*-LTR” genomic architecture (Fig. 1). Thus, the major difference between LTR retrotransposons and simple retroviruses is that the later include a third gene (*env*) for an envelope protein which confers infectious abilities to the retroviruses. However, some members of the families *Metaviridae*, *Pseudoviridae*, and *Belpaoviridae* also carry the *env* gene, suggesting that an LTR retrotransposon might become a retrovirus upon acquiring a third *env* gene. Among metaviruses, pseudoviruses and belpaoviruses with *env*, only those from the *Errantivirus* genus in the family *Metaviridae* have been demonstrated to generate infectious virions. Interestingly, the LTR retrotransposon-virus paradigm gets support also in the reverse path because a reverse-transcribing virus may become or act as an LTR retrotransposon when the *env* gene is lost and/or the machinery required for infecting other cells is neutralized. This is the case for most endogenous retroviruses (ERVs) of vertebrates, which usually derive from exogenous retroviruses that after colonizing the germ cells became unable to infect other cells due to accumulation of multiple mutations. Interestingly, the replication system of LTR retroelements (i.e., reverse-transcribing viruses and LTR retrotransposons) constituted by the members of the families *Metaviridae*, *Belpaoviridae*, *Pseudoviridae*, and *Retroviridae* is also related to that of reverse-transcribing viruses of the family *Caulimoviridae* which infect plants. Caulimoviruses are dsDNA viruses whose genome usually harbors two ORFs encoding for coat (*gag*) and *pol* polyproteins (Fig. 1), with domain features closely similar to those of metaviruses, pseudoviruses and belpaoviruses. These similarities suggest that caulimoviruses share a common evolutionary history with LTR retrotransposons and that caulimoviruses would be chimeric viruses resulting from recombination between a metavirus and another RNA virus or LTR retrotransposon that evolved to the status of a virus by recruiting new genes through horizontal transfer. In recognition of all the structural, functional and evolutionary relationships among the members of the families *Caulimoviridae*, *Belpaoviridae*, *Metaviridae*, *Pseudoviridae*, and *Retroviridae*, the ICTV has recently unified the five families into a single viral order, the *Ortervirales*.

Genome Organization and Functions of Gene Products and Other Structural Features

The full-length genome sequence of canonical LTR retroelements of the *Metaviridae*, *Pseudoviridae*, and *Belpaoviridae* families normally present two LTRs that flank an internal region of variable size (from 3 to 15 kb) that contains open reading frames (ORFs) for the encoded *Gag*, *Pol*, and/or *Env* protein domains (Fig. 1). The LTRs are two normally homologous non-coding sequences that usually begin and end in dinucleotide (5'-TG ... CA-3') inverted repeats. A typical LTR displays three regions: a U3 region of 200–1200 nt that contains the promoters; a region called “R” because it is repeated on each end of the transcript; and a U5 region of 75–250 nt that constitutes the first portion of the reverse-transcribed genome. Normally, the LTRs do not contain coding genes but present regulatory elements such as “enhancers” and “promoters” that regulate the expression of the genes in the internal region of the genome and also, in certain cases, the host genes. The internal region is usually delimited by two small motifs: a 18 nt sequence downstream to the 5' LTR called Primer Binding Site (PBS) and by another small region of ~10 A/G located upstream of the 3' LTR called “Polypurine Tract” (PPT). The internal region normally includes ORFs encoding for two polyproteins, *Gag* and *Pol*. The *Gag* polyprotein presents domains for the structural proteins including the capsid protein (CP), which forms the core of the Virus-Like Particle (VLP), and a nucleocapsid (NC) involved in RNA packaging through recognition of a specific region in the viral genome called Ψ . Curiously, Ψ is a frequent site of deletions in the proviral genome, giving defective VLPs which could generate non-infectious virions in some reverse-transcribing viruses with the entire LTR-*gag-pol-env*-LTR structure. On the other hand, *Pol* presents domains for distinct enzymes such as a protease (PR) belonging to the clan AA of aspartic peptidases that is required for proteolytic processing of the two *Gag* and *Pol* polyproteins; a reverse transcriptase (RT) involved in the reverse transcription synthesis of cDNA from the single-stranded RNA (ssRNA) template; a ribonuclease H (RH) responsible for the hydrolysis of the original RNA template that is part of the RNA/DNA hybrid generated during reverse transcription; an integrase (INT) needed for the integration of the proviral cDNA into the host genome. As also shown in Fig. 1, viruses in the *Metaviridae* and *Belpaoviridae* families usually present a common organization of *gag-pol* domains (CP-NC-PR-RT-RH-INT), which are also observed in retroviruses. The only difference between the two groups is that retroviruses additionally contain the matrix domain (MA) in the *Gag* polyprotein, upstream of the CP, which is not present (or at least not preserved at the domain level) in metaviruses and belpaoviruses (nor in pseudoviruses). The order of the RT and INT domains in the internal region of members of the *Pseudoviridae* family is different from that of metaviruses, belpaoviruses and retroviruses. While

Fig. 1 Representative elements of each family within the order *Ortervirales*. Simian immunodeficiency virus (SIV) of *Macaca mulatta* is taken as a complex retrovirus example of the family *Retroviridae*, where the typical accessory genes are colored green. Koala retrovirus (KoRV) is used as an example of a simple retrovirus in the family *Retroviridae*. Legolas and Gypsy are used as representatives for the family *Metaviridae*. Copia and Sire are shown as representatives of the family *Pseudoviridae*. Pao and Tas represent the family *Belpaoviridae*. The Cauliflower mosaic virus (CaMV) is provided as a representative of the family *Caulimoviridae*. Domain features of each *gag*, *pol*, and *env* region are indicated below each represented genome description. PBS and PPT acronyms mean Primer Binding Site and Polypurine Tract, respectively. MA, CP and NC acronyms in *gag* refer to Matrix, Capsid and Nucleocapsid domains, respectively. PR, RT, RH and INT acronyms in *pol* refer to Protease, Reverse Transcriptase, Ribonuclease H and Integrase domains, respectively. SU and TM acronyms in *env* refer to Surface and Transmembrane domains, respectively. P1, P2, P3 and P6 in caulimoviruses refer to Movement protein, Aphid transmission factor, Virion associated protein, and Transactivator/Viroplasm, respectively. For more examples of orterviral representative full-length genomes, visit the GyDB (<http://gydb.org>). In addition, Table 1 provides a summary of all members of the *Metaviridae*, *Belpaoviridae*, and *Pseudoviridae* families currently classified by the ICTV.

metaviruses and belpaoviruses usually present RT-RH domains upstream of INT, pseudoviruses present a distinct organization with the INT domain being interspersed between PR and RT domains. Besides the “LTR-gag-pol-LTR” domain architecture, many lineages of the members of the *Metaviridae*, *Pseudoviridae* and *Belpaoviridae* families additionally contain a third *env* ORF which potentially endows them with infectivity. In retroviruses, Env protein binds to a receptor on the target cell surface and this event triggers a conformational change which leads to the fusion of viral and cellular membranes. Furthermore, at least some *Metaviridae* members, such as those belonging to the Tat clade in plants, encode accessory proteins (similar to complex retroviruses), whose function, however, remains unclear.

Taxonomy, Phylogeny and Members of the Families

Classification of the distinct LTR retroelements or viruses in the order *Ortervirales* is performed by phylogenetic methods. In Fig. 2, we show the phylogeny of the *Ortervirales* inferred based on the Pol polypeptide domains. For simplicity, branches of caulimoviruses and retroviruses are collapsed. Each family splits into distinct phylogenetic lineages, herein referred to as clades or branches (they are bigger in terms of both OTUs - Operative Taxonomical Units - and host distribution). We use popular nomenclature to refer to each clade or branch in the tree. In the following section the taxonomic structure of each family is discussed in detail. As an additional information, Table 1 provides a summary of all members of the *Metaviridae*, *Belpaoviridae*, and *Pseudoviridae* families currently classified by the ICTV.

The *Metaviridae* family is composed of metaviruses (LTR retrotransposons) and pro-retroviruses (LTR retroelements with *env* gene but with no evidence of an infective behavior). Originally, the distinct elements belonging to the *Metaviridae* family were classified into three major genera: *Errantivirus* (Ty3/Gypsy elements with *env* gene), *Metavirus* (without *env*), and *Semotivirus* (Bel/Pao elements). This classification derives from the early discovery of Ty3-like LTR retrotransposons of fungi and their Gypsy-like Env-encoding relatives in drosophilids, followed by the characterization of other elements (including Bel/Pao elements) in multiple other eukaryotes. More recently, Bel/Pao elements (genus *Semotivirus*) were removed from the family *Metaviridae* because they do not form a monophyletic group with other *Metaviridae* members. The family *Metaviridae* needs further revision because the diversity of Ty3/Gypsy elements is much greater and more complex than previously thought. The genus *Errantivirus* includes Gypsy-like viruses of drosophila, which as shown in Fig. 2, forms a monophyletic clade splitting into at least two sub-clades (denoted as Gypsy and 17.6). Other Ty3/Gypsy elements form distinct clades, including Athila, Osvaldo and Tor4a, and encode for a third ORF showing structural features typical of Env polypeptides, such as the large Surface (SU) domain providing antigenic sites rich in cysteines, the transmembrane (TM) domain near their carboxyl terminus, multiple putative N-glycosylation sites, and putative protease cleavage sites at conserved positions. These lineages are pro-retroviruses because they carry an *env* gene, albeit they do not cluster phylogenetically with errantiviruses but more properly with other Ty3/Gypsy lineages of LTR retrotransposons (thus, contradicting the errantivirus-metavirus classification). This is for instance the case of Athila clade of pro-retroviruses of plants that are a sister clade of LTR retrotransposons called Tat. Athila and Tat are supported as a monophyletic branch in all Ty3/Gypsy phylogenies (although Athila is a pro-retrovirus and Tat a metavirus). On the other hand, the phylogenetic relationships of all the Ty3/Gypsy lineages originally considered to constitute the genus *Metavirus* cannot be resolved based on current data due to the high sequence divergence in that family. Moreover, members of one of the largest and best supported branches of Ty3/Gypsy LTR retrotransposons, labeled *Chromovirus* in Fig. 2, differ from other Ty3/Gypsy elements in that (with very few exceptions, such as Ty3, TF1 and TF2) their INTs have a conserved chromodomain at the C-terminus. This branch of chromodomain-Ty3/Gypsy LTR retrotransposons are formally classified as representative members of the genus *Metavirus* but is widely referred to as the genus “*Chromovirus*” (because of their chromodomain INTs) and splits into at least three major branches widely distributed in plants, fungi and vertebrates herein referred to as “Plants”, “Algae” and “Fungi/Vertebrates” according to the host distribution of the corresponding elements. Another lineage traditionally classified within the genus *Metavirus* includes Mag – a large branch collecting different clades of Ty3/Gypsy LTR retrotransposons of metazoans. The remaining diversity of elements originally assigned to the genus *Metavirus* is distributed across a number of smaller clades (Cer-like, Mdg3/Micropia, 412/Mdg1, Osvaldo/Gmr1, CsRN1, Tor-like and others) (Table 1).

The *Belpaoviridae* family groups all the Bel/Pao LTR retrotransposons and pro-retroviruses of the belpao family formerly classified by the ICTV as the genus *Semotivirus* within the family *Metaviridae* because they present the same *gag-pol* organization as metaviruses (Fig. 1). However, belpaoviruses are significantly divergent on the sequence level from metaviruses and they constitute a well supported monophyletic branch that falls outside of the *Metaviridae* family. Taking this into consideration, the ICTV has recently moved the *Semotivirus* genus from the family *Metaviridae* into a separate family, the *Belpaoviridae*, within the order *Ortervirales*. Based on current data, belpaoviruses are less diverse than their metavirus counterparts, albeit their currently known diversity is also greater than previously supposed. Based on the Pol tree shown in Fig. 2, five clades can be defined: Pao, Sinbad, Bel, Tas, and Suzu. Of these, Pao, Sinbad, and Suzu clades group together in a well supported branch. The relationship of this branch with the two other clades (Bel and Tas) remains unresolved. Bel and Tas clades mainly include LTR retrotransposons. However, within Tas clade, some elements, such as Tas (the element that gives the clade its name), carry an ORF encoding for a putative Env polypeptide, suggesting that at least some belpaoviruses might be able to form infectious virions.

The *Pseudoviridae* family is also highly diverse and includes all Ty1/Copia LTR retrotransposons and pro-retroviruses. At present, the ICTV recognizes three genera within the *Pseudoviridae* – *Pseudovirus*, *Hemivirus*, and *Sirevirus*. Although these three genera are well supported in the current phylogeny, they are not sufficient to cover the whole diversity of Ty1/Copia LTR retroelements. Based

Fig. 2 Phylogeny of members of the order *Ortervirales* based on an alignment concatenation of the most conserved part or cores of the four pol polyprotein domains (PR-RT-RH-INT) of 268 OTUs belonging to the *Retroviridae*, *Caulimoviridae*, *Metaviridae*, *Pseudoviridae*, and *Belpaoviridae* families. OTUs are collapsed in clades except for those elements providing clusters of a single OTU, which are represented with their name in gray and italicized. Families and genera currently recognized by the ICTV are provided in bold italics. The absence of an INT domain in the alignment is represented with a gap in the pol alignment. For simplicity, bootstrap information is provided only for the most internal nodes of the tree and only when bootstrap values are higher than 50. Families collecting true or potential retroviruses or LTR retrotransposons are highlighted in red. The figure is adapted from Fig. 1 in Llorens C., *et al.* 2009. The full expanded version of this tree in web format is available as Supplemental file 1 in Llorens C., *et al.*, 2009. The web version of this tree provides information about names, Genbank accessions and hosts of all LTR retroelement taxa used. By clicking on each OTU in the pol tree, the reader can access the accession of the requested element from GyDB or NCBI, respectively. Although our current knowledge about the diversity of *Ortervirales* is still incomplete, this Pol tree provides an acceptable and realistic perspective on their evolutionary history, mainly because of the strong phylogenetic signal of the RT, which is the pol domain most frequently used to infer retroelement phylogenies in general. With reasonable variations due to differences in rates of evolution, this evolutionary history is also supported by gag (the other protein domain common to all *Ortervirales*) and by other proteins encoded by these LTR retroelements. Readers interested in more specific details about the evolutionary history of the order *Ortervirales* can visit GyDB and access a comprehensive collection of phylogenetic trees inferred based on all encoded products of these LTR retroelements. The figure is adapted from Fig. 1 in Llorens, C., Muñoz-Pomer, A., Bernad, L., Botella, H., Moya, A., 2009. Network dynamics of eukaryotic LTR retroelements beyond phylogenetic trees. *Biology Direct* 4, 41. The full expanded version of this tree in web format is also provided as Supplemental file 1 in that article.

^aGyDB [<http://gydb.org>].^bThe clade "Chromovirus" is often considered a different genus.

on the Pol tree shown in Fig. 2, Ty4 and Ty2 clades form a branch which is representative of the *Pseudovirus* genus, Copia clade represents the genus *Hemivirus*, whereas Oryco and Sire clades form a group constituting the *Sirevirus* genus. The remaining lineages constitute small clades whose relationships remain unresolved. Finally, the clades designated as CoDi-like include four different Ty1/Copia lineages described in the diatom *Phaeodactylum tricornutum*. It is worth mentioning that Ty1/Copia elements in the CoDi-I clade, similar to Ty3/Gypsy chromoviruses, encode INTs containing a chromodomain at their C-terminus.

Life Cycle and Replication

The life cycle of all LTR retroelements consists of four steps (Fig. 3): (1) transcription and protein synthesis, (2) RNA packaging and VLP formation, (3) reverse transcription, and (4) integration. In the first step, integrated copies of the LTR retroelement are transcribed by the cellular RNA polymerase II. The transcription initiates from a promoter located in the 5' LTR and then, the full-

retroelement mRNA is translated into the Gag and Pol polyproteins that are proteolytically processed by PR to release mature CP, NC, INT, and RT-RH proteins (Pol can be expressed as a translational fusion with Gag or through one or more ribosomal frameshifting).

During the second step of RNA packaging and VLP formation, translated Pol peptides and two copies of full-length mRNA are typically encapsidated together with a specific cellular tRNA involved in priming into a VLP assembled using Gag peptides. The CP oligomerizes to form the immature capsid, while NC packages the genome. The initial VLP assembly is driven by the uncleaved Gag polyprotein, ensuring that the full-length retroelement mRNA is recruited and encapsidated, allowing the Gag-RNA-Gag interactions, contributing to the assembly of an immature Gag/ribonucleoprotein (Gag-RNP) particle. The immature VLP is subsequently matured by proteolytic cleavage of PR between CP and NC domains. Current evidence suggests that the VLPs assembled by metaviruses, pseudoviruses and belpaoviruses might not be infectious when applied extracellularly (except for errantiviruses) but we cannot dismiss further evidence to change this interpretation. Note for instance that the vast majority of fungal RNA viruses are not infectious when applied extracellularly. Yet, they are still considered viruses. The capsids of LTR retroelements play a protective role against defense systems of the host cell during the subsequent steps of the life cycle. Note that in contrast to retroviruses which are released from the host cell to the environment, LTR retrotransposons do not have an extracellular stage in their life cycle, similar to most fungal and some plant viruses. However, high-resolution structures of recently determined immature and mature Ty3 VLPs have shown a close structural similarity between the capsids of metaviruses and retroviruses. Based on the sequence conservation of the CP and NC domains, this similarity can be also extended to all other members of the order *Ortervirales*.

In the third step of reverse transcription, the full-length retroelement mRNA serves as a template for the synthesis of cDNA within the VLP. As also shown in Fig. 3, the cellular tRNA (packaged in the VLP) anneals to the retroelement mRNA at the PBS region that is complementary to the 3' end of the tRNA and is used by RT as a primer to synthesize the (–) DNA chain complementary to the R-U5 zone of 5' LTR. The tRNA primes the reverse transcription of a short minus-strand species of DNA referred to as the minus-strand-strong-stop (–SSS). As this cDNA is being synthesized, RH degrades the RNA template once it is reverse transcribed. Degradation of the 5' end of the RNA releases the –SSS from the 5' end of the RNA and allows it to anneal to the R sequence at the 3' end of the same RNA or other co-packaged genome. This positions the –SSS to be extended by RT to generate the minus-strand of the LTR-retroelement. The remainder of the RNA is degraded by RH with the exception of the PPT adjacent to the 3' LTR, sequence that confers to RNA fragment resistance to RH cleavage. This 3' PPT RNA serves as the plus-strand primer for reverse transcription. Plus strand cDNA is synthesized until 5'-end of the minus strand, and the PBS sequence of tRNA is employed as a template before producing a plus strand strong-stop DNA (+SSS). The +SSS is transferred to the 3' end of the minus strand previously generated and then, the tRNA primer is removed by the RH activity. The complementary sequences of PBS at the 3' ends of the +SSS and of the minus strand generated mate with each other and a circular structure is formed. Each strand serves as a template for RT extension until the double strand DNA is full-length synthesized and LTR ends are duplicated.

During minus strand synthesis most recombination events take place, when the –SSS fragment is transferred from 5' end of an RNA to R sequence at 3' end of a genetically distinct RNA. This process, together with several mutations accumulated by the low fidelity of RT, promote viral evolution and confer to the virus a better capacity to escape from host system. In contrast, other non beneficial mutations for the virus are also produced. For example, in retrovirus such as HIV several mutations in PPT sequence have been observed, what has been correlated to low infectious levels.

It is worth returning to the priming mechanism to highlight that the tRNA complementarity of the PBS varies within each family and depending on the element. For instance, the PBS for errantiviruses is predicted to normally be complementary to a tRNA^{Ser}, with a notable exception of the Gypsy element that presents a PBS with complementarity to a tRNA^{Lys}. In contrast, plant chromoviruses normally use a tRNA^{Met} as a primer, whereas chromoviruses of fungi and vertebrates use a selfpriming mechanism (also depicted in Fig. 3), with some exceptions such as Ty3 which is though to be primed by the tRNA^{Met}. The self-priming mechanism of fungal and vertebrate chromoviruses has been extensively studied in elements such as TF1. According to this model, the first 11 nt of the mRNA are complementary to its PBS and act as a primer of the –SSS cDNA synthesis.

The fourth step of integration takes place when the reverse transcription is completed (as also illustrated in Fig. 3(A)). During this step, the double-stranded cDNA is imported from the VLP into the nucleus and is inserted into a chromosomal target site, usually generating a 5 bp duplication of host target DNA. Integration is catalyzed by the retroelement INT (which belong to the superfamily of DDE INTs) in two reactions: 3' processing and strand transfer. During the 3' processing reaction, the INT removes two or three nucleotides from the 3' ends of the cDNA to position the highly conserved CP dinucleotide at the 3' end of the cDNA. In retroviruses and some LTR-retrotransposons, the tRNA primers initiate reverse transcription two or three nucleotides from the LTR and this results in the addition of deoxynucleotides at the cDNA termini that the INT subsequently removes during this reaction. In other cases, such as the TF1 LTR retrotransposons, the minus-strand primer initiates reverse transcription with no extra nucleotides added before the LTR.

With respect to the strand transfer, reverse-transcribing viruses seem to direct the integration of their genome in specific locations, suggesting that it is not a random process. This event could be in benefit of viruses, when cDNA integration takes place into particular active genes. This leads to viral clonal expansion and persistence in the infected cells. Active genes are usually located in the nuclear periphery where chromatin regions are in an open conformation. Activity of integrated LTR promoters depends on the open chromatin to make it accessible for the binding of the different transcription factors. On the other hand, integration of cDNA is able to disrupt or alter gene functions, with potential detrimental effects on the viability of host cells and, by extension, viability of the inserted LTR retroelement (which depends entirely on the well-being of the host cell). However, in

the course of evolution, LTR retroelements have developed mechanisms to specifically target integration without altering the gene functions. This is primarily achieved by integration into noncoding regions, preferential targeting of heterochromatin regions (not permissive for transcription) or by association with centromeric regions. For example, Ty1 and Ty3 retrotransposons of *S. cerevisiae* integrate near sites of RNA polymerase III (pol III) transcription by recognizing pol III transcription complexes or chromatin states associated with pol III transcription. By contrast, TF1 recognizes certain RNA polymerase II (pol II) promoters. The great majority of Gypsy elements are located in the pericentromeric regions of the *D. melanogaster* genome and this location is conserved in strains from different geographic origins thus suggesting that a high number of Gypsy elements are non-mobile and were already present in the pericentromeric sequences of the common ancestor of the *D. melanogaster* strains. The accumulation of metaviruses such as Athila/Tat and chromoviruses in centromeric sequences is also observed in plants. Recent studies have shown that the chromodomain specifies the target site preference of chromoviral LTR retrotransposons by the recognition of characteristic chromatin modifications. These mechanisms for silencing of the viral genomes are also used to contribute to viral latency and to escape from the immune system. For instance, human immunodeficiency virus (HIV), a retrovirus that targets integration into heterochromatin regions, makes association with alphoid pericentromeric regions in different chromosomes, or integrates its genome in an orientation opposite to the host gene transcriptional readthrough.

Host Range and Evolutionary Dynamics

Phylogenies tend to separate metaviruses, pseudoviruses, belpaoviruses, caulimoviruses, and retroviruses into five well defined phylogenetic clusters to which we refer as families within the order *Ortervirales*. Such perspective is consistent with the idea of gradual evolution and, although accurate, it is based solely on the phylogenetic signal coming from the gag and Pol polyproteins and, inherently, does not consider other biological and evolutionary phenomena that probably played a relevant role in shaping the diversity of the *Ortervirales*. These include: (1) modularity, the distinct genes and/or genomic regions of a virus/LTR retrotransposon usually present different rates of evolution, (2) chimerism, different events of gene recruitment, genome rearrangement and recombination that can be traced in the evolution of the *Ortervirales* at different evolutionary times, (3) alternance of horizontal and vertical means of transmission; while eukaryotes usually transmit their LTR retroelement communities via germ lines (i.e., by vertical means), exogenous retroviruses and caulimoviruses spread via infection (i.e., horizontally) and there is evidence that several LTR retrotransposons might have been able to protagonize some episodes of horizontal transmission, (4) clonal interference and competition with other viruses and other self genetic elements, and (5) co-evolution with eukaryotes; different cellular and molecular host environments that arose at distinct evolutionary times in plants, fungi and animals have forced the distinct orterviral communities to adapt depending on the changes in host environment. All these considerations lead to a scenario of reticulate evolution suggesting that our comprehension of the history of the *Ortervirales* is far from complete and could be more accurately traced as a phylogenetic network shaped by a range of changes in the cellular and molecular environments provided by eukaryotes to their retrotransposable parasites that reciprocally were also key for eukaryotic evolution. In Fig. 4, we superimpose the Pol tree previously shown in Fig. 2 over the evolutionary history of eukaryotes. For simplicity, we divide the resulting tree into three major temporal ranges to provide the reader with a system biology macroevolutionary perspective of the origin and evolution of members of the order *Ortervirales* undergoing three major evolutionary transitions in their eukarotic hosts.

The first transition covers events from the earliest eubacterial organisms around 3500 million years ago (MYA) and the first unicellular algae to the diversification of eukaryotes into the major supergroups (approximately 2170–1950 MYA) between the Archean and the Proterozoic periods (as shown in Fig. 4). Current sequencing projects show that *Metaviridae* chromoviruses are present in multiple distinct algae, amoebae, chromalveolates, fungi, plants and animals. The most parsimonious hypothesis for such a wide distribution is thus that early members of the family *Metaviridae* have already existed before the split between plants and unikonts (1550 MYA) and that chromoviruses might constitute the oldest branch within this family. Sequencing projects also show pseudoviruses to be widespread among algae, plants, fungi and animals, suggesting that pseudoviruses co-existed with metaviruses during this transition. Thus, the ultimate origins of the ortervirads likely took place at the onset of eukaryogenesis and involved combination of gag and pol genes with the LTR features to raise an ancestral LTR retrotransposons from which pseudoviruses and metaviruses diverged into two independent but stable lineages following the genomic relocation of the *int* gene that distinguishes the two families.

The second transition covers a period of 1330–380 MYA from the Proterozoic to the Phanerozoic, during which eukaryotes underwent key events of diversification, such as the divergence between primitive animal phyla (e.g., Porifera, Cnidaria, Ctenophora) and the more complex animals, including the emergence of eumetazoans, the Cambrian explosion, the divergence between arthropods and priapulids, the rise of vertebrates, the emergence of land plants and the establishment of plant-fungal interactions. Respecting the *Metaviridae*, although chromoviruses are present in vertebrates, such as fish, in amphibians and in amniotes, they are absent in the known genomes of cnidarians, mollusks, protostomes and basal deuterostomes. However, we find others metavirus lineages. For example, Mag and other elements, from which we have apparently emerged before the split of bilaterians into protostomes and deuterostomes (761–531 MYA). It is currently unclear whether chromoviruses were driven to extinction in protostomes, echinoderms and urochordates or were horizontally transmitted from plants or fungi to vertebrates. Horizontal transmission seems to be a good explanation for vertebrate chromoviruses, taking into account the strong similarity to their fungal relatives, but if so, such an event might be as ancient as the split of osteichthyes into actinopterygians and sarcopterygians

Fig. 4 Evolutionary history of LTR retroelements superimposed over the evolutionary history of eukaryotes. The tree of Ty3/Gypsy LTR retroelements is traced in blue; Ty1/Copia elements yellow; Bel/Pao black; *Retroviridae* violet; and *Caulimoviridae* green. This representation defines the natural origin and distribution of the *Ortervirales* constrained by the evolutionary history of eukaryotes and also includes information about diverse reticulate events in the evolutionary history of LTR retroelements. Host ranges are indicated in red. The framework has been divided into three major eukaryotic transitions (colored in gradient of gray) to interpret the distribution of the distinct LTR retroelement families and communities on the basis of the most likely ages of their hosts. GYA refers to billions (giga) years ago. The distinct evolutionary paths traced in this figure only reflect the host distributions of the distinct orterviral families and their likely times in those hosts, not extinction events. For example, if a host range is represented in the second transition but not in the third one, it indicates that that orterviral family is inhabiting the genomes of those hosts from that age to the present time. Adapted from Llorens, C., Muñoz-Pomer, A., Bernad, L., Botella, H., Moya, A., 2009. Network dynamics of eukaryotic LTR retroelements beyond phylogenetic trees. *Biology Direct* 4, 41. with permission from BioMed Central, part of Springer Nature.

(410–415 MYA). Regarding the *Pseudoviridae*, sequencing projects reveal pseudoviruses to be also widespread in cnidarians, arthropods and deuterostomes. However, to our knowledge, there is no evidence of pseudoviruses in platyhelminthes and nematodes, suggesting that metaviruses underwent more explosive diversification in metazoans compared to pseudoviruses. As for the *Belpaoviridae*, their wide distribution in metazoans and their absence in fungi and plants suggests that the origin of belpaoviruses probably predates the split between primitive animals and higher eumetazoans (1300–380 MYA). With respect to the emergence of *bona fide* retroviruses (family *Retroviridae*), sequencing projects reveal three *Retroviridae* lineages including gammaretroviruses, epsilonretroviruses and spumaretroviruses to overlap with chromoviruses in fishes, amphibians and sauropsids thus suggesting that the first *Retroviridae* emerged in marine vertebrates before the Osteichthyes split into the actinopterygians and the sarcopterygians. We can thus assume that metaviruses and pseudoviruses have radiated into a variety of lineages, with belpaoviruses and the *Retroviridae* emerging during this second transition.

The third eukaryotic transition (range in light gray within Fig. 4) covers a period from the Paleozoic era (330 MYA) to the present, a timeframe which included the origin of first gymnosperms (360–248 MYA), the split of amniotes into sauropsids and synapsids (330–312 MYA), the diversification of winged insects (380–325 MYA) and the origin of flowering plants (160–90 MYA). New levels of complexity and ecosystems probably accompanied the aforementioned events in the evolutionary history of eukaryotes, activating parallel radiations of LTR retrotransposons as well as the emergence of new viral and retroviral forms to colonize the new host environments such as those of synapsids (mammals and their extinct relatives). Consistent with this perspective, sequencing projects revealed that metaviruses and retroviruses overlap in sauropsids but there is no trace of functional metaviruses, pseudoviruses or belpaoviruses in mammals. The only orterviral family known to spread in mammals is the family *Retroviridae*, albeit several host genes, most notably including the neuronal gene *Arc* which evolved from the CP domain of domesticated metaviruses, can also be detected in the mammalian genomes. This suggests that while metaviruses were co-opted and driven to extinction by synapsids, the retroviruses co-evolved with their hosts, recruiting new accessory genes to adapt their infective means of transmission to the new and more complex mammalian host environments. In parallel, mammals evolved more sophisticated mechanisms of innate immunity to combat retroviruses. Retrovirus accessory genes and mammalian mechanisms of innate immunity will be best understood when considered as the joint products of macro-evolutionary conflicts played out over a geological scale. During this period, other retroviral forms, such as errantiviruses, also emerged from the *Metaviridae* family in winged insects such as *Drosophila*, albeit the lower biological complexity of insects (in comparison to that of mammals) allowed the diversification of the metaviruses in other lineages as well as the expansion of pseudoviruses and belpaoviruses in these and other insects. A very similar perspective is found in plants. In this particular, gymnosperms and angiosperms show massive radiations of *Athila/Tat*-like metaviruses and LTR retrotransposons to overlap with their chromoviral counterparts and with pseudoviruses which also show some examples of protoretroviral forms, such as some elements belonging to Sire clade. Thus, pro-retroviruses might have emerged in plants before the divergence of gymnosperms and angiosperms. On the other hand, phylogenetic and comparative genomic analyses of *gag-pol* regions also support the evolution of caulimoviruses from the *Metaviridae* (note in Fig. 2 how the *Caulimoviridae* are rooted within the *Metaviridae*). However, the genomes of caulimoviruses additionally present other genes, such as the one encoding for the movement protein, which are necessary for the viral life cycle and transmission of these viruses in plants. While it is not yet clear whether the ancestors of caulimoviruses were inhabitants of plants or insects (the latter act as mechanical vectors), the origin of caulimoviruses was probably concomitant with the emergence of insects and flowering plants (130–90 MYA). These two events probably gave an opportunity to metaviruses to explore other gene combinations and viral strategies from which caulimoviruses probably emerged (recruiting new genes or recombining with other viruses).

Impact and Relationships of LTR retrotransposons and Retroviruses With Their Hosts

Until recently, LTR retrotransposons were considered to be merely molecular parasites whose sole aim is to self-replicate in the host genomes and be transmitted from one host generation to another. Current evidence suggests, however, that the co-evolutionary history of LTR retrotransposons and their hosts is much more complex than previously thought. Retroelements with and without LTRs are mutagens, whose activities might lead to diverse genetic alterations, including: (1) gene knockouts, (2) modifications of gene expression, (3) epigenetic reprogramming, (4) insertions and deletions, (5) structural rearrangements, and (6) segmental duplications. To avoid potential damages to their hosts, LTR retroelements have developed specific mechanisms to integrate the retrotranscribed cDNAs into non-coding genomic regions, as discussed above. The mechanisms ensuring specific insertion of LTR retrotransposons are the basis of a co-evolutionary history that has permitted these elements to successfully proliferate in their eukaryotic hosts. In sharp contrast, the host may benefit from the new insertions of retroelements because they are a constant source of new sequence substrate. In plants, for instance, the metaviruses and the pseudoviruses constitute the major fraction of all plant transposons. This fraction is, in fact, correlated with the genome size in some groups of plants, such as angiosperms, thus providing a potential explanation why the amount of DNA in a haploid genome does not match with the complexity of these taxa (i.e., the C-value paradox). The situation is similar in other plant, fungal and animal taxa across the Tree of Life. In humans, for example, endogenous retroviruses (HERVs) constitute approximately 8% of the human genome. If we also consider the rest of retrotranscribing elements (with and without LTRs) and related sequences, the fraction reaches up to 45% of the human genome.

The contribution of new sequence substrate as a consequence of the mobilization of retrotransposable elements can help the host organism to explore new levels of complexity. Integration of multiple copies of LTR retroelements and other mobile genetic elements into a particular chromosomal region may result in repeat clusters, which are hotspots for chromosomal rearrangements and segmental duplications due to erroneous homologous recombinations during mitosis and meiosis. Understanding these clusters is still lacking but they appear to provide for genome plasticity to their hosts. Notably, several fungal pathogens, such as *Leptosphaeria maculans* or *Verticillium dahlia*, have been able to take advantage of these plastic loci for evolving increased virulence and pathogenesis, and adapt better to changing environments than members of these species lacking the corresponding clusters.

The sequences contributed by retroelements as a consequence of their mobilization is not only a source of new substrate but also of variability from which new genetic combinations and functions may emerge and be co-opted by the host, giving rise to new genes and regulatory elements, able to rewire the gene expression networks of eukaryotes. In parallel, a functional equilibrium must exist to regulate the activities of retrotransposable elements, to avoid the disruption of the normal regulatory mechanisms of gene expression and pathways. The loss of this equilibrium may have severe consequences, leading to developmental disorders and diseases. In humans, for example, the activation and mobilization of HERVs and other reverse-transcribing elements have been associated with cancer, autoimmune diseases, genomic instability and neurodegenerative diseases, including Tau pathology and Alzheimer. In *D. melanogaster*, the mobilization of *Gypsy* and *Copia* elements (*Metaviridae* and *Pseudoviridae*, respectively) has also been correlated with the activity of Tau, rendering *D. melanogaster* an excellent model to explore the molecular mechanisms behind diseases associated not only with neurodegenerative processes but also with tumorigenesis and tumor immunity. The relationship between cancer and retroelements is, in fact, object of current research both in humans and in other taxa. For instance, some reverse-transcribing viruses, such as retroviruses, have shown strong preference to integrate into genes encoding cellular transcription factors involved in cell growth. BACH2 and MKL2 are two of the proteins encoded by the genes where retrovirus integration has been observed. Integration into these genes alters their functions and increases the life-time and survival of the host cell. In particular, rearrangements of these genes have been associated to proto-oncogenic activities. In other taxa, like *Mya arenaria*, a soft-shelled clam characteristic of many areas in the North Atlantic, a fatal leukemia-like disease of unknown origin has been reported to be catalyzed by the expression of *Steamer*, an LTR retrotransposon of the *Metaviridae* family. Therefore, the proper regulation of gene activation and silencing has an extreme importance for the co-existence of LTR retroelements and the hosts they inhabit. To this end, host genomes and transposable elements may both exist in variable DNA methylation states whose differential transcription is modulated by distinct types of regulatory elements, such as enhancers, silencers and chromatin insulators. Of these, chromatin insulators play a central role in the proper regulation of gene expression and organization of chromosome architecture. A well studied example of chromatin insulator in *D. melanogaster* is the insulator of *Gypsy*-like errantiviruses, that is able to modulate enhancers and promoters. Uncontrolled expression of *Gypsy* may result in insertions of this retrovirus with negative consequences on the normal expression patterns of the host genes. To keep *Gypsy* under control, *Drosophila* implements an RNA interference (RNAi) system constituted by Piwi and *flamenco*, a locus that is the source of antisense small RNAs interacting with Piwi to repress the expression and infective properties of *Gypsy*. The repressive role of *flamenco* in *Drosophila* also extends to other metaviral and pseudoviral elements whose expression is also modulated by this system.

Concluding Remarks

Viruses and mobile genetic elements oftentimes represent different faces of the same coin. This is the case of the members of the families *Metaviridae*, *Pseudoviridae*, and *Belpaoviridae* which may exist as LTR retrotransposons and as potential or even true viruses that share origins and evolutionary history with other reverse-transcribing viruses, such as vertebrate retroviruses and plant caulimoviruses. In recognition of this evolutionary connection, the ICTV has recently grouped the *Belpaoviridae*, *Metaviridae*, *Pseudoviridae*, *Retroviridae*, and *Caulimoviridae* families into a single viral order, the *Ortervirales*. In this article, we have reviewed what is currently known about metaviruses, pseudoviruses and belpaoviruses, with the aim to provide the reader with a systems biology perspective on these viruses and discuss the deep evolutionary history of the *Ortervirales*. Although retroviruses and caulimoviruses have been extensively studied, our understanding of the real impact of reverse-transcribing viruses in eukaryotes is still in its infancy. Due to this reason, the members of the families *Metaviridae*, *Pseudoviridae*, and *Belpaoviridae* present excellent opportunities not only to investigate the origin and evolution of reverse-transcribing viruses in plants, fungi and animals but also to investigate their roles as inductors of disease, regulatory elements and vectors of complexity and evolution in plants, fungi and animals.

This is an update of R. Hull, Rice Tungro Disease, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00714-7.

Glossary

Agro-inoculation Infection of a plant by injecting Agrobacterium containing a modified Ti plasmid into which an infectious copy of the viral genome has been inserted. In the case of pararetroviruses, this infectious copy comprises the sequence that can express the more-than-full-length RNA transcript required for the reverse transcription stage of viral replication.

Pararetrovirus A virus that replicates by reverse transcription but differs from retroviruses in that it encapsidates the DNA phase of replication and that virus replication does not require integration of the viral genome into the host chromosome.

RNA Interference (RNAi) RNAi is an evolutionarily conserved sequence-specific natural defense mechanism in plants against transposable elements and intracellular

pathogens such as viruses, targeting the cellular or viral double-stranded RNA (dsRNA). In this process non-coding small RNAs degrade viral and cellular transcripts, resulting in post-transcriptional gene silencing. These small RNAs are formed as a result of cleavage or slicing of dsRNA or RNA having strong secondary structures by host ribonucleases and are called small interfering RNA and microRNA.

Semi-persistent transmission Virus-vector interaction in which the vector acquires the virus rapidly upon feeding and the acquisition period is relatively short, typically less than a week. The virus is believed to interact with components of the vectors' mouthparts or foregut.

Silencing suppressor Viral proteins that counteract host RNAi defense by inhibiting key steps of cellular RNAi pathways.

Introduction

Rice tungro disease is caused by a complex of two viruses, Rice tungro bacilliform virus (RTBV), which is a member of the family *Caulimoviridae* and Rice tungro spherical virus (RTSV), a member of the family *Secoviridae*. The viral complex is transmitted by several species of green leafhoppers in a semi-persistent manner. The genomes of RTBV and RTSV are double-stranded DNA and single-stranded RNA respectively and are replicated using very different mechanisms. Genetic resistance against RTBV has not been characterized, but for RTSV, recessive resistance has been mapped to a gene encoding a translational initiation factor. We are reviewing here the status of knowledge for the disease and for both viruses.

Rice Tungro Disease

The characteristic symptoms of rice tungro disease had been reported from several South-East Asian countries for many years before they were recognized in 1963 to be of viral etiology. During and since the 1960s, there have been several severe outbreaks of the disease mainly associated with the major agronomic improvements in rice cultivation resulting from the 'green revolution'. The disease is found in all countries of South and South-East Asia and in the South and South-East of China (Fig. 1(A)). The importance and distribution of the disease are evidenced by the variety of local names for it: *accep na pula* (Philippines), *mentek* (Indonesia), *penyakit merah* (Malaysia), yellow-orange leaf (Thailand), leaf yellowing (India). In the early 1990s, it was estimated that tungro caused annual losses in excess of \$1.5 billion without taking account of the cost of insecticide to control the vector. In parts of India, the disease causes losses of up to 50% of the expected crop yield.

In most of the rice cultivars, tungro infection is manifested by stunting and reduced tillering, yellow to orange-yellow leaf discoloration beginning from the leaf tip and extending towards leaf base, delay in flowering, failure of panicle emergence and rust-colored patches or twisted leaves in some cases. Infection to a young rice plant is more severe with mottled appearance and interveinal chlorosis as compared to an old rice plant having rust-colored specks of varying sizes. A typical view of a paddy field showing tungro symptoms is shown in Fig. 2. The disease symptoms are often mild or almost absent in tolerant rice varieties. The disease is transmitted in a semi-persistent manner by several leafhopper species with the rice green leafhopper (GLH), *Nephotettix virescens* (Fig. 3), being the most important vector. It is also transmitted by *Nephotettix cincticeps*, *Nephotettix nigropictus*, *Nephotettix malayanus* and *Recilia dorsalis*; these other vectors may be of relative importance in certain situations. The distribution of the disease is circumscribed by the distribution of *N. virescens* (Fig. 1(A)).

It was not until 1978 that it was recognized that tungro is caused by a complex of two viruses, Rice tungro bacilliform virus (RTBV) and Rice tungro spherical virus (RTSV). RTBV alone causes severe disease symptoms in the host but it cannot be transmitted by GLH in the absence of RTSV. RTSV, on the other hand, can be transmitted independently by GLH (Fig. 4) but causes only mild stunting

Fig. 1 (A) Distribution of rice tungro disease in Asia and the circle shows the distribution of the main rice tungro disease leafhopper vector. (B) Phylogenetic trees of complete sequences of RTBV (top) and RTSV (bottom). The percentage of identity relative to the first sequence is indicated.

Fig. 4 Rice tungro virus transmission. (A) RTBV cannot be transmitted on its own by GLH; (B) RTSV can be transmitted on its own by GLH but cause very less or negligible symptoms to appear; (C) An RTSV harboring GLH is able to transfer RTBV alone and the presence of both RTBV and RTSV causes visible symptoms.

symptoms. The dependence of RTBV upon RTSV for transmission suggests the presence of a “helper component” in RTSV or RTSV-infected cells. The origin, nature and functional properties of the above “helper component” remains elusive.

Rice Tungro Bacilliform Virus

Taxonomy

RTBV is a dsDNA pararetrovirus belonging to a mono-specific genus, *Tungrovirus*, in the family *Caulimoviridae*.

Transmission and Host Range

GLH transmits RTBV in a semi-persistent manner in rice only in the presence of RTSV. However, cloned RTBV DNA can be transmitted to rice plants if inoculated using agrobacterium, even in the absence of RTSV. This process is known as agro-inoculation. Till now, this method has not been used to investigate the host range of RTBV.

Structure

RTBV consists of bacilliform particles of about 130 nm length (though there can be longer ones in some isolates) and 30 nm diameter (Fig. 5). The particle structure is based on a $T = 3$ icosahedron cut across its threefold axes, the tubular portion being made up of rings of hexamer subunits with a repeat distance of about 10 nm.

Fig. 5 Particles of RTBV (long particles) and RTSV (spherical particles) negatively stained in uranyl acetate. The bar indicates 100 nm.

Fig. 6 The genome organization of RTBV and the different transcripts associated with it. The innermost circle represents the double-stranded 8 kb DNA. The numbers inside the circle represent the position of the nucleotide ($\times 1000$) on the genome. The approximate sites of the two discontinuities D1 and D2 are marked. The position of the four open reading frames, ORF I, ORF II, ORF III and ORF IV, are represented as arcs. The proteins encoded by ORF III polyprotein have been marked. MP: Movement protein; CP: Coat protein; PR: Protease and RT/RNase H; Reverse transcriptase/ribonuclease H. The arc in orange represents pre-genomic RNA. The blue-green arc represents the spliced ORF IV RNA. The dotted arcs represent the intronic region of the transcript.

Genome

The RTBV genome is a double-stranded circular DNA of an approximate size of 8 kb (**Fig. 6**). It has high resemblance with badnaviruses and caulimoviruses, in having site-specific discontinuities one on each strand of the double stranded circular genome, a poly-protein analogous to retroviral gag-pol and involvement of an RNA intermediate in replication.

The RTBV genome potentially has four Open Reading Frames (ORFs) viz., ORF I (P24), ORF II (P12), ORF III (P194) and ORF IV (P46) named according to the sizes of the proteins they encode. The transcription of RTBV genome is asymmetric with one strand (containing the minus-strand priming site) possessing all the coding capacity. The ORF I, II and III are compactly arranged and have a coinciding start-stop signal (ATGA). The ATG of this signal acts as a start codon for downstream ORFs and TGA of this signal codes for stop codon for the upstream ORF. The third ORF encodes for a poly-protein, which is cleaved subsequently to produce four different proteins. A short non-coding intergenic region separates the ORF III from ORF IV, which is expressed from a

spliced RNA. ORF I and ORF IV are also separated by a long intergenic region which includes the single RTBV promoter, the signal for poly-adenylation, various short ORFs and the splice donor site.

Functions of Proteins

The 24 kDa protein (P24) encoded by ORF I is poorly characterized till date although it is reported to play some role in viral particle assembly. P24 interacts with the host D1 protein, associated with photosystem II, which may affect the host photosynthetic machinery, leading to the appearance of tungro-associated symptoms.

The ORF II encodes for a 12 kDa protein (P12), which is shown to interact both *in vivo* and *in vitro* with the coat protein domain of the ORF III encoded poly-protein and plays a role as a protein scaffold in the assembly of the virus capsid.

The longest ORF of RTBV is the ORF III, which encodes for a polyprotein having four clear-cut domains for movement protein (MP), coat protein (CP), aspartate protease (PR) and reverse transcriptase/ribonuclease H (RT/RNase H) arranged clockwise on the genome map.

The presence of an ORF IV downstream of the gag-pol analog of retroviruses is the single feature that differentiates RTBV from other badnaviruses. ORF IV possesses an unconventional isoleucine (ATT) start codon rather than the canonical methionine ATG codon and is expressed as a spliced product in association with small ORF I. ORF IV encodes for a 46.2 kDa (P46) protein, which acts as a viral suppressor of RNA silencing, affecting the cell-to-cell spread of the RNA silencing signal.

The viral coat protein comprises one major species of Mr 37 kDa; this may be processed to give a product of Mr about 33 kDa and possibly others. The molecular mass of the coat protein has been measured by mass spectrometry and the N- and C-terminal sequences have been determined. This protein contains two specific amino acid sequence motifs, CXCX₂CX₄HX₄C characteristic of reverse transcribing virus gag proteins and CX₂CX₁₁CX₂CX₄CX₂C unique to badnaviruses and tungroviruses.

Genome Variability

There are 13 complete nucleotide sequences of RTBV available in databases till date, four from India and nine from South-East Asia. The genome sizes of the South-East Asian isolates are slightly more (~100 bp) as compared to the Indian isolates. The molecular as well as the nucleotide and amino acid sequence based phylogenetic analyses of these RTBV isolates have now grouped them into several clusters; those from India forming a distinct cluster (Indian strains), whereas the rest are more diverse (Fig. 1(B)). The Indian strains of RTBV showed divergence from the rest due to several insertions, deletions and substitutions, mostly in the intergenic regions. A replication mechanism with the absence of proof-reading may be a plausible reason for the slight variations among these isolates. The sequence variability of RTBV genomes is similar to those of badnaviruses, such as banana streak virus, dioscorea bacilliform virus and cacao swollen shoot virus. For badnaviruses, virologists consider 80% as the similarity threshold to differentiate species. If this threshold is applied to RTBV, 7 species would exist among the 13 complete genome sequences (Fig. 1(B)), including three in the Philippines alone. Therefore, we would have a single disease, the Rice Tungro Disease, associated with several different viruses, a situation very similar to badnaviruses. The situation is completely different for RTSV, where all the six complete sequences from three countries (Philippines, Malaysia and India) are within 90% similarity or above (Fig. 1(B)).

Virus-Host Relationships

Host plants, upon infection with viruses, launch an RNA-based defense response against the virus, which leads to degradation of the viral transcript into 21–24 nucleotide fragments, which are called viral si (small-interfering) RNAs. This degradation is sequence-specific and viral siRNAs initially formed by the recognition of RTBV transcript for degradation, leads to an amplification of further degradation in a sequence-specific manner, resulting in the accumulation of copious amounts of siRNAs from RTBV in infected rice plants. This finally results in a gradual fall in RTBV levels in a few weeks' time. Certain regions of the RTBV genome, namely the portion immediately prior to ORF I, the 5'-untranslated region (5' UTR), gives rise to a large amount of siRNA, as compared to other regions of the genome. Despite the production of large quantities of siRNAs, the RTBV transcripts largely escape degradation because the 5' UTR folds into a strong degradation-resistant secondary structure. This could be a new type of escape employed by RTBV against host defense, not generally seen in other viruses.

Control

There are three major approaches to controlling tungro; by the manipulation of various cultural practices such as planting time, having a crop-free period, and seedbed protection; invasion of young susceptible rice plants by viruliferous GLH can be avoided. Spraying insecticide can control the leafhoppers but this has not proved to be particularly effective. There have been various programs to breed resistance to tungro but most have proved of limited success. The International Rice Research Institute Philippines, has screened more than 40,000 accessions of rice for resistance to tungro viruses and have found two basic types of resistance, that to the vector and that to the virus. Since RTBV and RTSV occur together in the plant, breeding efforts have not been directed against exclusively RTBV or RTSV, but both together. Resistance to the vector has also been used, but has proved to be not very durable.

In addition to the breeding-based approach, transgenic strategies have also been employed, targeting RTBV. With the development of the concept of pathogen derived resistance (PDR), in 1980s, there has been several attempts to confer resistance against RTBV through generation of transgenic plants containing virus-derived genome fragments or full-length genes. Both protein-mediated and RNA-mediated strategies of PDR have been used for generating virus resistant transgenic plants. The movement protein gene, the coat protein (CP) genes, protease or the viral replicase genes have been exploited for initiating successful PDR. The proteins or their parts act as a dominant negative competitor during the infection of virus. RNA-based approaches have been used, using the concept of RNA-interference (RNAi). Rice plants expressing an RNAi construct against RTBV ORF IV have been produced, which show only mild symptoms upon GLH-mediated inoculation of both RTBV and RTSV. This resistance has been recently diversified into several popular rice varieties of southern India by marker-assisted breeding and many of the progenies have acquired the resistance along with the transgene, which is characterized by almost 1000-fold fall in the titers of RTBV upon GLH-mediated inoculation, when compared to the titers seen in non-transgenic rice plants of the same variety. The above plants do not show any fall in RTSV titers. A similar approach has also been used to generate transgenic rice plants expressing RNAi constructs targeting both RTBV and RTSV simultaneously, which, as expected, show resistance against both the viruses. However, it needs to be emphasized that all the work involving transgenic rice plants described above, have been conducted under controlled laboratory or green house conditions and are yet to be validated in the field.

Biotechnological Applications

Viral promoters, such as CaMV 35S, find wide application as expression modules for heterologous genes in plants. The potential of RTBV promoter, which has a similar overall location in the viral genome as CaMV 35S, has been explored. RTBV promoter shows tissue-specific activity, specifically in the phloem, in transgenic rice plants generated with a construct wherein a reporter gene is driven by the upstream sequences of the RTBV ORF I taken from a Philippine isolate. Further work with an Indian isolate of RTBV identified a complex arrangement of positive and negative regulatory elements in the promoter region, some of which were located downstream to the transcription start site. These constructs have potential use in driving heterologous gene expression in transgenic rice plants, and possibly in other monocot species.

Transient gene silencing in plants can be achieved by the use of viral vectors, utilizing the phenomenon of RNAi. This phenomenon is termed Virus Induced Gene Silencing or VIGS. RTBV genome has been modified suitably to develop a VIGS system for rice. Using this system, any rice gene can be silenced in a transient manner and its effect can be studied, giving the investigator a glimpse of its function in the plant. This approach has important applications in revealing gene functions in the rice plant.

Rice Tungro Spherical Virus

Taxonomy

RTSV belongs to the genus *Waikavirus*, in the family *Secoviridae*, in the order *Picornavirales*.

Transmission and Host Range

RTSV appears to have a restricted host range limited to members of the Poaceae and Cyperaceae (*Echinochloa crus-galli*, *E. glabrescens*, *E. colona*, *Leptochloa chinensis*, *Leersia hexandra*, *Oryza sativa*, *Panicum repens*, *Cyperus rotundus*); RTSV causes few, if any, symptoms in these hosts.

Structure

RTSV has isometric particles having a diameter of 30 nm (Fig. 5). The virus is limited to vascular tissues where it is restricted to the phloem cells. Virus particles are scattered in the cytoplasm or are embedded in non-enveloped electron-dense granular inclusions. Particles also occur as crystalline aggregates often in vacuoles. Small vesicles containing fibers are found in the cytoplasm, usually along the wall of infected cells.

Gene Functions

The capsid is made up of three coat protein species (CP1, CP2, and CP3) that are apparently in equimolar amounts, and is thought to have a similar T = 1 icosahedral architecture to that of picornaviruses. Identification of cleavage sites by N-terminal sequencing shows that CP1 is 22.9 kDa and CP2 is 22.3 kDa; the C-terminus of CP3 has not been identified. In Western blots of crude extracts from infected plants, an antiserum to CP3 identifies a band at 33 kDa and several in the range 40–42 kDa; the nature of these larger bands is unknown. The genome is translated into a poly-protein, which is processed to give various products including the three coat protein species, a putative type III helicase, a cysteine or 3C-type protease, and an RNA-dependent RNA polymerase at its 3' end. Functions of other products have not yet been determined. No functions have been ascribed to the products of the 30 short ORFs and there is no evidence that these are expressed.

Genome Diversity

Unfortunately, there is not a lot of sequence information available for RTSV, there are however 6 complete genome sequences originating from three countries and all sequences are 90% similar or greater (Fig. 1(B)), indicating that they most probably all belong to the same species.

Genome

Each RTSV particle contains one molecule of single stranded positive-sense RNA of about 12.2 kbp. The RNA encodes a large poly-protein of about 393 kDa and has two short ORFs at the 3' end (Fig. 7). A total of six nucleotide sequences, representing the full RTSV genome are available in the NCBI Nucleotide database (June 2019) of which three are from India, two from Philippines and one from Malaysia (Fig. 1(B)). RTSV strain Vt6 overcomes the resistance to the type strain in rice cultivar TKM6. Several serological variants of RTSV have been reported. Molecular techniques reveal much micro-variation in the sequences encoding CP1 and CP2 but there is no evidence for major geographic strains that reflect those of RTBV. Comparatively speaking, RTSV is much more conserved than RTBV, when sequences available from various regions of South and South-East Asia are compared.

Virus-Host Relationships

Recently, the virus-derived siRNAs have been studied in rice infected with both RTBV and RTSV using high throughput sequencing. Despite a reasonably large quantity of such siRNAs accumulating in the infected plants against RTBV, the accumulation of the corresponding siRNAs against RTSV is extremely low. This study points towards possibly an uncharacterized mechanism of escape from the siRNA-mediated resistance response of the plant by RTSV.

Control

Natural resistance in rice against RTSV is conferred as a recessive trait controlled by the translation initiation factor 4-gamma gene (eIF4G). Three residues of eIF4G, Y¹⁰⁵⁹ V¹⁰⁶⁰ V¹⁰⁶¹ are known to be associated with resistance against RTSV. Using CRISPR/Cas9 system in the RTSV-susceptible variety IR64, mutations in eIF4G, have been generated to confer resistance against RTSV. These mutations were located adjacent to the YVV residues and were successfully transmitted to the next generations. However, these approaches have yet to be used at the field level to effectively control RTSV.

Concluding Remarks

RTBV and RTSV are a unique combination of unrelated viruses, which have come together to cause the Tungro Disease, one of the most important crop diseases. Tungro has the potential to cause major disruptions in the production of rice in south and South-East Asia, thereby posing a threat to food security in this part of the World. The functions of the proteins encoded by the two viruses are yet to be worked out in detail. Recent research has revealed a novel role for RTBV P24 as an RNAi suppressor, hence possibly acting as a virulence factor for the virus. Despite the above RNAi suppressor being active, RNAi-mediated resistance has been demonstrated against RTBV and RTSV in rice under experimental conditions. Such studies can have

important applications in controlling the viruses and hence the Tungro Disease. Other important aspects of the viruses, namely the semi-persistent transmission of the viral complex by the vector GLH and the potential helper function mediated by RTSV for the transmission of RTBV are, however, still shrouded in mystery.

This is an update of E. Hebrard, D. Fargette, G. Konate, Rice Yellow Mottle Virus. In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00715-9](https://doi.org/10.1016/B978-012374410-4.00715-9).

Introduction

Rice yellow mottle virus (RYMV) is a member of the genus *Sobemovirus* in the family *Solemoviridae*. RYMV is present only on the African continent. It was first reported in Kenya in 1966 and in Côte d'Ivoire in 1974 in irrigated rice fields. Since the early 1990s, RYMV is present everywhere where rice is grown in sub-saharan Africa and in Madagascar. It affected all types of rice cultivations, including lowland, upland rainfed, floating and mangrove rice. RYMV regularly induces severe yield losses to rice production ranging from 20% to 100%. In some regions, when epidemics are recurrently very severe, farmers abandoned their fields and planted new rice fields. Highly susceptible cultivars have been eliminated by the disease. RYMV is now ranked as the main biotic threat to rice production in Africa.

Virion Properties

RYMV has icosahedral particles of 25 nm in diameter ([Fig. 1](#)). The virion particles are composed of a single coat protein (CP) of 29 kDa, a genomic RNA (gRNA), and one subgenomic RNA (sgRNA) molecule. The capsid contains 180 copies of the coat protein subunit arranged with $T = 3$ symmetry. The structure of RYMV was determined by X-ray crystallography at 2.8 Å resolution and compared to the structure of Southern cowpea mosaic virus (SCPMV) and Sesbania mosaic virus (SeMV). As for other sobemoviruses, RYMV CP subunits are chemically identical but structurally not equivalent. Three types of CP subunits termed A, B, C are related by quasi three-fold axes of symmetry and are involved in different inter-subunit contacts. In the C-type subunits, a longer part of the N-terminus is ordered (residues 27–49), forming an additional β -strand named β A arm. Sobemovirus particles are stabilized by divalent cations, pH-dependent protein-protein interactions, and salt bridges between protein and RNA. Upon alkali treatment in presence of chelators, the capsid shell swells and becomes sensitive to enzymes and denaturants. In these conditions, RYMV is more stable than SCPMV. This property is likely due to the 3D swapping of the RYMV β A arm around the distal quasi-six-fold axes as found with SeMV whereas the SCPMV β A arm makes a U-turn and is localized around the nearby quasi-six-fold axes. Another reason for the better stability of RYMV is likely to be the strong RNA-protein interactions resulting from the presence of ordered RNA within the capsid shell. RYMV particles exist in three forms with different stability (1) an unstable swollen form dependent on basic pH but lacking Ca^{2+} , (2) a transitional compact form dependent on acidic pH, but also lacking Ca^{2+} and (3) a stable compact form that is pH independent and contains Ca^{2+} . The compact form is highly infectious and probably required for virus movement and transport by vector.

Molecular diversity of the CP was analysed in relation to the capsid three-dimensional structure in order to identify which amino acids are involved in the differential recognition by certain monoclonal antibodies. The residues in position 178 and 180, despite their internal localisation in the capsid, can modify the antigenic reactivity, with Mabs G and E allowing serotypes Sr3 and Sr5 to be differentiated.

Organization of the Genome

The genomic RNA is one single-stranded messenger-sense molecule, ca. 4450 nt in size. The 5'-terminus of the RNAs has a genome-linked protein (VPg), and lacks a poly(A) tail. RYMV often encapsidates, in addition to its genomic and subgenomic RNA, a small circular satellite RNA (satRNA), that is dependent on a helper virus for replication. RYMV satRNA has 220 nt and it is a viroid-like RNA. No link between the RYMV satRNA and its pathogenicity has been demonstrated.

Like other sobemoviruses, the RYMV genome is organized in 5 overlapping open reading frames (ORF) ([Fig. 2](#)). Two non-coding regions at the RNA extremities contain 80 and 289 nt, respectively. The ORF1 and the ORF3 are localized at the 5' and 3'-extremities, respectively. An intergenic region of 12 nt separates ORF1 and ORF3. All the following coding regions overlapped two by two (ORF3 and ORF2a, ORF2a and ORF2b, ORF2b and ORF3).

The ORF1 encodes a protein P1 which is dispensable for replication but is required for systemic movement in plants. Moreover, RYMV P1 displays multiple functions in silencing by locally suppressing transgenic silencing but enhancing the local and systemic spread of silencing in the non-host plant *Nicotiana benthamiana* and inhibiting the DCL4-dependent endogenous siRNA pathway when transgenically expressed in rice.

The putative protein encoded by ORF3 is predicted to be translated from a leaky scanning and a non-AUG initiation. As for all the sobemoviruses, the protein Px has not been detected in infected plants and its function is unknown.

Fig. 1 RYMV capsid structure. The capsid comprised 180 copies of one single type of polypeptide arranged in $T = 3$ quasi-equivalent symmetry. The icosahedral asymmetric unit contains three subunits: A (in blue), B (in red) and C (in green). Each subunit is involved in different inter-subunit contacts. This image was automatically generated from VIPER virus capsid PDB file 1F2N using the MultiScale extension to the Chimera interactive molecular graphics package. Reproduce from Goddard, T.D., Huang, C.C., Ferrin, T.E., 2005. Software Extensions to UCSF Chimera for Interactive Visualization of Large Molecular Assemblies, Structure 13 (3), 473–482. Shepherd, C.M., Borelli, I.A., Lander, G., *et al.*, 2006. 3rd, Reddy VS., VIPERdb: A relational database for structural virology. Nucleic Acids Research 34, (Database issue), D386–9.

Fig. 2 RYMV genomic organization. Positions of the open reading frames (ORFs) are indicated in nucleotides. P1, protein X (Px), proteinase (Pro), VPg, RNA-dependent RNA-polymerase (Pol) and coat protein (CP) are labelled. The dotted line at nucleotide 1979 represents the frameshifting signal. The fusion point of the polyprotein P2a + b is unknown, and an AUG codon present at the beginning of the ORF2b (nucleotide 2093) is indicated by the vertical line.

The polyproteins encoded by the RYMV ORF2 are presumably translated from leaky translation. The start codon of ORF2 appeared to be in a more favorable context than ORF1. The ORF2b is translated as a polyprotein fused with ORF2a after a -1 programmed ribosomal frameshifting mechanism. The presence of a heptanucleotide slippery sequence UUUAAC and a predicted stem-loop structure are necessary. The ORF2a encodes the proteinase, the VPg and two putative proteins P10 and P8, the ORF2b encodes the RNA-dependent RNA-polymerase. RYMV proteinase contain the consensus sequence $H(X_{32-35})[D/E](X_{61-62})TXXGXSG$ characteristic of serine proteinases, they cleave between E-T and E-S amino acid residues. RYMV VPg is covalently linked to a serine, is characterized by the presence of a conserved $W[A/G]D$ sequence followed by a D- and E-rich region and can be phosphorylated. The interaction between the VPg and the rice eukaryotic translation initiation factor eIF4(iso)G1 is needed for a successful infection. The VPg and the P8 protein are intrinsically disordered. The localisation of the polymerase was predicted from the presence of the GDD motif and surrounding conserved motifs characteristics of RdRp.

The ORF3 is translated from the subgenomic RNA and encodes the coat protein (CP). RYMV CP is dispensable for replication but required for movement to long-distance likely through encapsidation. This movement was suggested to occur during the cell differentiation to vessels. The N-terminal sequence contains a putative bipartite nuclear localisation signal (NLS). This highly basic region is thought to interact with viral RNA and to stabilize the virion but virus like-particles (VLP) can be formed.

Relationships of the Species With Other Taxa

The species *Rice yellow mottle virus* belongs to the genus *Sobemovirus* in the family *Solemoviridae*. The genus contains 19 definitive species including *Southern bean mosaic virus*, the type species. The sobemovirus CPs are related to those of necroviruses (*Tombusviridae*) whereas the proteinase, VPg and polymerase are related to those of poleroviruses and enamoviruses (*Luteoviridae*).

Biological Properties

The natural host range of RYMV is restricted to a few members of the Poaceae family, principally *Eragrostidae* and *Oryzae* sp. The most commonly cited species are *Oryza sativa*, *O. glaberrima*, *O. longistaminata*, *O. barthii* and *Echinochloa colona*. A few additional Poaceae plants have been infected experimentally.

RYMV particles are present in all plant parts including roots and seeds. Particles are present in large amount in mesophyll cells, and in vascular tissues mainly in xylem and associated parenchyma cells. Particles were found individually, as aggregates, or as crystalline forms in the cytoplasm and the vacuoles of infected cells. In addition, the cytoplasm of infected cells contains fibrillar material located either in vesicles or distributed in diffused patches. Virus particles are also found in mature xylem, as well as inside the primary wall.

Cytological changes were found in the chloroplasts of infected mesophyll cells where the starch grains decreased in size and number. The chloroplasts form invaginations containing mitochondria, peroxisomes and virus particles. Electron dense materials were observed in the nuclei and associated with fibrillar elements in cytoplasmic vesicles. The most dramatic changes induced by RYMV occurred in the cell walls of parenchyma and mature xylem cells causing disorganisation of the middle lamellae wall. From infected cells, a viral ribonucleoprotein complex moves from cell-to-cell to reach the vascular bundle sheath. Viral replication, encapsidation and storage in vacuoles occur mainly in vascular parenchyma cells. The calcium linkage from pit membranes to virus particles during xylem differentiation could contribute to disruption of these membranes and facilitate systemic virus transport. In the upper leaves, virions are suspected to cross the pit membrane to infect new vascular cells and virions spread out by cell-to-cell movement through plasmodesmata. At this stage of infection, most replication occurs in mesophyll and vascular cells, and most of the virions accumulate in large crystalline patches.

Vector transmission is mainly due to coleoptera vectors such as *Chaetocnema* spp., *Sesselia pusilla* et *Trichispa sericea*, but other biting insects including the grasshopper *Conocephalus* have been reported to occasionally transmit the virus. Transmission is not persistent. The virus is present within the seed, although RYMV is not seed-transmissible. Other transmission modes have been also reported through animals like rats, common in rice fields, or cows and donkeys, used for field work or during grazing. Abiotic transmissions through plant residues, irrigation water, guttation water, wind, direct contact between plants and contamination by infected agricultural tools have been observed. Experimentally, mechanical transmission is easily achieved.

Diagnostic and Identification

RYMV diagnosis was first based on symptoms. However, many factors such as mineral deficiencies can induce symptoms of yellow mottle on rice. Therefore, several tools for specific detection of RYMV were developed. First, polyclonal antibodies (PABs) directed against different isolates were used in double-diffusion tests and in direct antibody sandwich enzyme linked immunosorbent assay (DAS-ELISA). No cross reactions with other sobemoviruses was observed, demonstrating the high specificity of these antibodies. Western-blot analysis can be used to detect RYMV with PABs. These antibodies were also used in immunolocalisation techniques. Immuno-printing tests derived from the direct tissue blotting technique were developed to analyse the distribution of the virus in entire leaves. Moreover, cytological detection of RYMV CP in rice tissues can be performed by immunofluorescence microscopy after glutaraldehyde/paraformaldehyde fixation and labelling with secondary antibodies linked to fluorescein. Polyclonal antibodies directed against P1 produced in *E. coli* are also available, and were used in Western-blot analyses. Monoclonal antibodies were also developed to study RYMV diversity. Indirect triple antibody ELISA (TAS-ELISA) with strain-specific MABs allows the major serotypes to be differentiated.

In parallel to the serological methods, molecular tools were developed. The first full-length sequence was obtained after RNA extraction from purified virus. Several specific primers were defined to perform RT-PCR amplification and to produce infectious transcripts. Northern and Southern blot methods are available using a DNA probe obtained by PCR amplification of the CP gene (ORF4) from the infectious clone CIa. *In situ* hybridisation tests of the RNA in rice tissues were also performed. In this case, the probe was DNA, obtained from the full-length genome of the clone CIa labelled randomly with digoxigenin-UTP. Real time-RT-PCR assay is also available using primers in the conserved ORF2a. RT-PCR amplification of the CP gene followed by direct DNA sequencing progressively has replaced other molecular methods of analyses.

Epidemiological Aspects

Typical symptoms of RYMV are a mottle and a yellowing of the leaves. However, streaks, necrosis, and whitening are sometimes observed with some cultivars and under specific growing conditions. Infection resulted in stunting of the plant, reduced tillering, poor panicle exertion and sterility. Death of the plants of susceptible cultivars occurs after early infection. Severe yield losses ranging from 20% to 100% after RYMV infection have been reported in several countries. Most cultivars currently grown are susceptible to RYMV. Heavy infection is associated with reduced fertility.

RYMV is an emergent disease. It is thought that the virus was originally harboured in wild Poaceae and transferred only recently to cultivated rice. The rapid and intense spread of the virus was associated to the change of agricultural practices in response to increasing food demand. Very productive but susceptible *O. sativa* cultivars have been introduced from Asia which allows two crop

Fig. 3 Descriptive model of RYMV epidemiology. (1). Environment. RYMV is present in the environment in rice stubble and regrowths and in wild *Poaceae*. (2). Rice seedbeds. Primary infection occurred via biotic transmission (beetles, rats, cows) whereas cultural practices contribute to secondary infection in seedbeds. (3). Rice fields. Primary infection occurred via biotic transmission from the environment, and also when transplanting infected seedlings from seedbeds. Both biotic and abiotic transmissions contribute to secondary spread in rice fields. After harvesting, RYMV is perpetuated in contra-season in the environment through rice stubbles and regrowths and transmitted to wild *Poaceae*. From Hébrard, E., Fargette, D., Konaté, G., 2008. Rice Yellow Mottle Virus. In: Mahy, B.W.J., Van Regenmortel, M.H.V. (Eds.), *Encyclopedia of Virology* third ed. Oxford: Academic Press, pp. 485–490.

cycles a year resulting in the maintenance of the inoculum all over the year. RYMV propagation probably occurs as follows: (1) a virus source made of volunteers, of wild *Poaceae* or plant residues act as primary inoculum; (2) a direct contamination of the new rice fields occurs after mechanical transmission by man or biological infection by insects; (3) rice beds can also be infected by insect vector; (4) the new rice field originating from these infected seed-beds are contaminated by man during replanting; (5) further propagation of the virus is done by man animals, wind and irrigation water.

The epidemiology has been little studied and there are even uncertainties about the respective importance of biotic and abiotic transmission (Fig. 3). Under these conditions, precise forecasting of RYMV infection is not possible although growing intensification of rice cultivation in Africa will no doubt favour RYMV spread, unless durable resistant cultivars are introduced. Phytosanitary measures are sometimes advised although they are often economically not practicable and their impact to reduce virus spread is unknown. They include protection of seed-beds by nets, disinfection of tools used at replanting, destruction of volunteers and rice residues. Chemical control of the vectors is not economically feasible, is ecologically dangerous, and is most unlikely to be successful considering the large number of species involved in transmission.

Several breeding programs have been conducted in order to select and breed resistant cultivars. The genotype and the phenotype of two kinds of natural resistance have been characterized. Partial resistance is encountered in cultivars of *Oryza japonica* species with a delayed virus multiplication and symptom expression. Partial resistance is polygenic and a major quantitative trait locus has been identified on chromosome 12. High resistance has been identified in a limited number of accessions of *Oryza glaberrima* and two *O. sativa indica* species. No symptoms are apparent and virus content is most often undetectable. Three resistance genes have been identified. The recessive gene *RYMV1* that maps on chromosome 4 encodes the translation initiation factor eIF(iso)4G1. Compared to susceptible varieties, the resistance alleles are characterized by a point mutation and/or a small deletion in the conserved domain of the gene. The VPg was identified as the virulence factor, it interacts directly with eIF(iso)4G1 in susceptible plants. The *RYMV1* resistance was efficient against some of the representative isolates of the main virus strains. However, resistance-breakdown was reported in experimental conditions depending on the viral strain and the resistance allele. A single point mutation was sufficient to break the resistance but negative epistasis can inhibit the virulence emergence. The amino acid located at position 49 of the VPg reflects inter-species adaptation of the viral strains and has indirect effects on resistance durability. The recessive resistance gene *RYMV2* is homologous to the *Arabidopsis thaliana* gene for Constitutive expressor of Pathogenesis-Related genes-5 (CPR5), a nucleoporin controlling defense mechanisms. *RYMV2*-mediated resistance is conferred by a null allele. The virulence factor is the polyprotein P2a. The dominant resistance gene *RYMV3* was mapped in a 15 kb interval in which a CC-NBS-LRR domain-containing protein was annotated. Recently, a hypervirulent pathotype able to overcome all natural sources of high resistance has been identified in West-Central Africa. Transgenic plants with portions of the ORF2 expressing partial resistance have also been produced. This transgenic resistance is thought to involve a gene silencing mechanism. However, the transgenic lines showed a less effective, partial and temporary resistance compared to natural resistances.

Fig. 4 Phylogeny of RYMV. Phylogenetic tree inferred by maximum likelihood from the full sequences of 48 isolates representative of the genetic diversity and geographic distribution of RYMV in Africa. The different strains identified in West Africa (S1ca, S1wa, S2, S3, Sa, Sg) and East Africa (S4et, S4lm, S4lv, S4mg, S4ug) are differentiated by color. Strong bootstrap support of the nodes (>80%) is indicated.

Diversity and Evolution

The diversity of RYMV was assessed by studying isolates from several countries where the disease has been observed. The sequences of more than 500 CP genes are now available. Forty-eight isolates representative of the geographic and molecular diversity were fully sequenced. RYMV is a highly variable virus and analyses of the geographic distribution of the genetic diversity elucidated the process of evolution and of dispersal of the virus. RYMV showed a high level of population structure marked at the continental scale with two subdivisions: East-Africa and West-Africa (**Fig. 4**). The highest diversity was observed in East-Africa, with a pronounced peak in Eastern Tanzania, and a decrease from the east to the west of the continent. This pattern suggests a westward expansion with a succession of founder effects and subsequent diversification phases. Accordingly, genetic diversity would be adversely affected by recurrent bottlenecks occurring along the route of colonization, resulting in the lowest diversity in the extreme west. This, together with accumulation of *de novo* mutations postdating population separation, provides an explanation for the genetic differences among strains across Africa. The geographical overlaps between several strains would explain the recent detection of some recombination strains.

Glossary

Satellite RNA or satellite DNA A subviral genome dependent on a helper virus for both replication and encapsidation.

Satellite virus A subviral genome dependent on a helper virus for its replication but encoding its own capsid protein.

Satellite-like RNA A subviral genome dependent upon another virus for replication and encapsidation but is required for vector transmission of the helper virus.

Virophages Double-stranded DNA that depend on giant viruses for their replicate in co-infected eukaryotic cells.

Virus-associated nucleic acid A subviral genome that depends on another virus for encapsidation and transmission, but not for its replication.

Introduction

Satellites are a diverse collection of subviral agents that are capable of attenuating or exacerbating disease symptoms caused by their cognate helper viruses (HVs). Satellites can be differentiated from other subviral nucleic acids, such as sub-genomic (sg) RNAs, defective (d) or defective interfering (di) RNAs, and viroids, by their molecular, biological, and genetic nature. Unlike sgRNAs, dRNAs, and diRNAs, satellites and viroids have little or no sequence similarity to any known virus, except for the terminal regions. Whereas viroids are replicated by host polymerases, RNA satellites rely on the HV's polymerase for their replication. Satellites have been found associated with DNA and RNA viruses, and in the latter case, with both ssRNA and dsRNA viral genomes, the satellites being of the same nucleic acid type as the HV. While, in general, the HV can exist independent of the satellite, there are exceptions where a satellite contributes to the transmission of the HV and thus is referred to as being satellite-like. In addition, some viral RNAs and DNAs are found in association with other viral genomes on which they depend for their encapsidation and transmission, but not for replication. These viral RNAs and DNAs are referred to here as virus-associated nucleic acids. True satellites are divided basically into two main groups; those that encode their own capsid protein (CP) are called satellite viruses, while those that rely on their HV for both replication and encapsidation are referred to as satellite RNAs or DNAs (satellite nucleic acids). There are also satellites of satellites, in which some satellite RNAs are replicated by the HV but are encapsidated by the CP of a satellite virus. In addition, in the case of turnip crinkle virus (TCV, genus *Betacarmovirus*, family *Tombusviridae*), which replicates both satellite RNAs and diRNAs, it also produces a chimeric RNA (referred to as satC) that is in part a diRNA and in part a satellite RNA (satD). While most satellites are found in association with plant viruses, a few have been found in association with animal, fungal or protist viral genomes. Most plant viruses are not associated with satellites. However, the few that does have attracted significant attention due to the disease modulating roles of the associated satellites. With the advent of metagenomics, additional satellites have been identified prompting a revisit of their taxonomic classification to align them with that of *bona fide* viruses.

History

The use of the term satellite as a subviral agent was first conceptualized in 1962, to describe the relationship of a 17 nm diameter viral particle found in association with some isolates of the 26 nm diameter tobacco necrosis virus (TNV; genus *Alphanecrovirus*, family *Tombusviridae*). The smaller particle was dependent on TNV for its accumulation but was serologically unrelated to TNV. A few other satellite viruses have been described since then, but, in general, they are rare. By contrast, satellite nucleic acids are more common. The first satellite RNA was described in 1969, in association with tobacco ringspot virus (TRSV, genus *Nepovirus*, family *Secoviridae*), the satellite RNA being encapsidated by the CP of TRSV. The symptoms induced by TRSV were attenuated dramatically by the presence of the satellite RNA; but this is not always the case. Some satellite RNAs have no effect on either the accumulation or pathogenesis of the HV while a few may exacerbate the HV-induced disease. Most of these satellite RNAs contain ssRNA genomes, while a few contain genomes of dsRNA. Some of the satellite RNAs with ssRNA genomes are translated to produce proteins, which may or may not be required for their replication, depending on the specific satellite RNA. The first demonstration that satellite molecules are not limited to RNA viral systems was made in 1997 when a tomato leaf curl virus satellite (TLCV-sat-DNA) was characterized from disease-affected tomato plants in Australia. TLCV-sat-DNA is dependent on its TLCV HV for replication and encapsidation. In addition, it was shown that TLCV-sat-DNA replication was also supported by other taxonomically distinct geminiviruses, including the begomoviruses tomato yellow leaf curl virus (TYLCV) and African cassava mosaic virus (ACMV), and the curtovirus beet curly top virus (BCTV). Since then, additional classes of satellite DNAs have been characterized and described.

Geographical Distribution

The host range and geographical distribution of satellites mirror those of their HVs owing to the dependence of the former on the latter for genome replication and encapsidation. Similarly, satellite nucleic acids depend on the HV's transmission mechanism (including the dependence on arthropod vectors) for short and long-distance spread. Thus, the worldwide prevalence and distribution of satellite molecules draws from the global distribution of their HVs. Interestingly, alphasatellites and betasatellites are mostly associated with Old World monopartite geminiviruses, except for some alphasatellites that have been recently reported to occur in association with New World bipartite begomovirus infections.

Classification

Satellite viruses, satellite nucleic acids, virus-associated nucleic acids, and other satellite-like agents are very diverse in terms of their nucleic acid type, size, sequence, structure, or translatability. Satellite genomes may be composed of single or double stranded RNA or DNA molecules, which may be linear or circular. Whereas satellite viruses encode a CP for genome encapsidation, satellite nucleic acids depend on the CP of their HV for genome encapsidation. True satellites such as satellite viruses and satellite nucleic acids are dependent on the HV for their multiplication in co-infected host cells since they lack genes that encode functions needed for replication. Most or all portions of the genomes of true satellite, except for the terminal regions, are distinct from the genomes of their cognate HV.

Satellite-like nucleic acids are another class of subviral agents that differ from true satellites in that they encode a function necessary for the biological success of the associated virus. However, like the true satellites, they also are incapable of autonomous replication because they do not encode a replicase, with the exception of alphasatellites. Thus, they function primarily to remedy a deficiency in a defective virus and have sometimes been classified as part of the genome of the virus they assist. For instance, satellite-like RNAs associated with groundnut rosette virus (genus *Umbravirus*, family *Tombusviridae*) or beet necrotic yellow vein virus (BNYVV, genus *Benyvirus*, family *Benyviridae*) contribute to vector transmissibility of their associated viruses. Other classes of autonomously replicating nucleic acids (virus-associated nucleic acids) such as alphasatellites are dependent on their HV for encapsidation, cell-to-cell and long-distance movement and vector transmission. Thus, satellites do not constitute a homogeneous group and are traditionally not formally classified into species and higher taxa by the International Committee on Taxonomy of Viruses (ICTV). However, because several satellite molecules encode functional proteins, their taxonomy has been revisited to bring it in alignment with that of *bona fide* viruses. A list of currently known satellites categories is provided in [Table 1](#).

General Properties and Effects of Satellites

Satellite Viruses

Category 1: Chronic bee-paralysis associated satellite virus

Chronic bee-paralysis associated satellite virus (CBPVA; unassigned) is the only member of this group characterized to date ([Table 2](#)). The isometric particles of this satellite virus are found in bees infected with the HV, chronic bee-paralysis virus (CBPV), with CBPVA capable of interfering with CBPV replication.

Category 2: Satellites that resemble tobacco necrosis satellite virus (genera *Albetovirus*, *Aumavirus*, *Papanivirus* and *Virtovirus*)

The group consists of several plant-infecting satellite viruses that are found in association with taxonomically distinct HVs that used to be collectively known as the tobacco necrosis satellite virus or satellite tobacco necrosis virus (STNV) group. Recently, the ICTV recognized species belonging to this group and assigned them to the genera *Albetovirus*, *Aumavirus*, *Papanivirus*, and *Virtovirus*. Member belonging to these unassigned genera are found in association with ss(+)RNA plant HVs belonging to the genera *Alphanecrovirus*, *Aureusvirus*, *Panicovirus* (*Tombusviridae*), and *Tobamovirus*, (*Virgaviridae*) respectively (Table 2). These satellite viruses depend on their HVs for replication. With the exception of the rod-shaped *Tobacco virtovirus 1* (unassigned genus *Virtovirus*), particles of the plant satellite viruses are isometric, 17 nm in diameter, with a $T = 1$ symmetry, built of 60 protein subunits, as determined at high resolution by X-ray diffraction for *Tobacco albetovirus 1* (genus *Albetovirus*) and *Panicum papanivirus 1* (genus *Papanivirus*). Thus, the particle morphology of most satellite viruses differs from that of their respective HVs. In spite of the different structure of CP and virus particle, the particles of both the satellite and HV may share important properties; for example, the particles of *Tobacco albetovirus 1* can bind specifically to the zoospores of the vector fungus *Olpidium brassicae*. The ca. 1200 nt RNA of *Tobacco albetovirus 1* does not have a methylated cap structure or a genome-linked protein (VPg) in its 5' end. Unlike most plant virus RNAs, it has a phosphorylated 5' end. The 3' termini may share a structure with that of the HV genomic RNA (gRNA) as is the case for both tobacco mosaic virus and *Tobacco virtovirus 1* where their 3' termini form tRNA-like structures that are aminoacylable with histidine. Cis-acting sequences necessary for RNA amplification have been mapped at the 5' and 3' non-translated regions (NTRs) of *Panicum papanivirus 1* RNA as well as within the CP open reading frame (ORF), and are conserved in a defective RNA, which is maintained by this satellite virus. A translational enhancer domain has been mapped in the 3' NTR of albetoviruses. Like other satellite viruses, the isometric particle of *Maize aumavirus 1* (genus *Aumavirus*, unassigned) is 17 nm in diameter, but its CP has limited sequence similarity with orthologous proteins of other satellite viruses. Albetoviruses have been reported to interfere with each other's replication and with the accumulation of the HV. Satellite viruses can also modify the symptoms induced by the HV, as is the case with *Panicum papanivirus 1*, which in co-infection with Panicum mosaic virus (PMV) enhances the mild symptoms of the HV to cause severe mosaic and chlorosis in millet plants. Symptom induction is due to the *Panicum papanivirus 1* CP, and a chlorosis-inducing domain has been mapped. In addition to its structural and symptom-inducing functions, the CP of *Panicum papanivirus 1* is involved in systemic movement, binds PMV particles, and counters the effects of post-transcriptional gene silencing suppressors. Furthermore, the particles of albetoviruses may contain non-coding satellite RNA of about 620 nt, which depends on TNV for replication and on the satellite virus for encapsidation. A satellite RNA with similar dependence relationships has been described for PMV and *Panicum papanivirus 1*. These systems are good examples of the complexity of dependence relationships in satellitism.

Category 3: Nodavirus-associated satellite virus (genus *Macronovirus*, family *Sarothroviridae*)

Macrobrachium satellite virus 1 (genus *Macronovirus*; family *Sarothroviridae*) is the only currently recognized species of this group (Table 2), with extra small virus (XSV) as its representative member. XSV and its HV *Macrobrachium rosenbergii* nodavirus (MrNV) infect giant freshwater prawns and cause the debilitating and fatal white tail disease or white muscle disease in several countries. XSV is consistently found in co-infection with MrNV on which it depends for its replication. The linear, positive sense ssRNA genome of XSV is 796 nt in length and contains a short poly(A) tail of 15–20 nt at the 3' end. The non-enveloped virions of XSV are spherical (ca. 15 nm in diameter) and they are serologically and structurally different to those of MrNV. It encodes a single ORF that is translated into two CPs, one an N-terminally truncated version of the other. XSV and MrNV have also been detected in several species of aquatic insects that were sampled from infected freshwater prawn nursery ponds. In addition, the satellite and HVs can replicate in mosquito cell lines, suggesting that aquatic insects serve as vectors for their spread.

Category 4: Adenovirus-associated satellite virus (family *Parvoviridae*; genus *Dependoparvovirus*)

The genus *Dependoparvovirus* (family *Parvoviridae*) currently consists of eight ICTV approved species that are collectively known as adenovirus-associated satellite viruses (AAVs; Table 2). They are: *Adeno-associated dependoparvovirus A* (the type species), *Adeno-associated dependoparvovirus B*, *Anseriform dependoparvovirus 1*, *Avian dependoparvovirus 1*, *Chiropteran dependoparvovirus 1*, *Pinniped dependoparvovirus 1*, *Squamate dependoparvovirus 1*, and *Squamate dependoparvovirus 2*. Their non-enveloped icosahedral virion is 18–26 nm in diameter with the capsid consisting of 60 copies of CPs, encapsidating a linear, ssDNA(+/–) genome of about 4.7 kb in size. As their genus name implies, the AAVs are mostly (or thought to be likely) dependent on helper DNA viruses, most commonly an adenovirus or herpesvirus, for replication in co-infected cells of their mammalian, avian or reptilian hosts. Though ubiquitous in humans and most other vertebrates, AAVs are by themselves not associated with any known pathology.

Category 5: Mimivirus-associated satellite virus (genera *Mavirus*, *Sputnikvirus*, family *Lavidaviridae*)

The discovery of giant viruses (extremely large genomes) infecting protists also resulted in the identification of new satellite viruses. The family *Lavidaviridae* includes the Sputnik and Zamilon viruses and the Maverick-related virus (genus *Mavirus*); also called giant satellite viruses (17–30 kbp linear or circular dsDNA genomes). “*Lavida*” stands for large virus-dependent or -associated virus and refers to the property of Sputnik and other satellite viruses of depending on or associating with large dsDNA viruses. Sputnik virus was identified in an amoebal host in co-infection with its HV, *Acanthamoeba polyphaga mimivirus* (genus *Mimivirus*, family *Mimiviridae*). Though the icosahedral virus particle of Sputnik virus is only a tenth of the size of *Acanthamoeba polyphaga mimivirus*, the satellite virus may target the cytoplasmic replication factory of the giant virus and cause aberrant capsid phenotypes. As a result, the Sputnik virus was considered a viral parasite of a virus and named as “virophage”. This terminology has also been used to describe other satellites associated with giant viruses. Another typical feature of virophages is the presence of core genes in their genomes, a conserved set of six proteins or domains: major capsid protein (MCP), minor capsid protein (mCP),

ATPase, protease (PRO), helicase (HEL), and a zinc-ribbon-containing domain. Currently, the family *Lavidaviridae* is divided in the genera *Sputnikvirus* and *Mavirus* with two and one species, respectively (Table 2).

Satellite Nucleic Acids and Satellite-Related Nucleic Acids

Category 6a: Satellite ssDNA (family *Alphasatellitidae*; subfamilies *Nanoalphasatellitinae* and *Geminialphasatellitinae*)

The recently created family *Alphasatellitidae* consists of circular single stranded DNA (ssDNA) molecules of approximately 1–1.4 kb that are associated with nanoviruses (subfamily *Nanoalphasatellitinae*) and some geminiviruses that belong to the genera *Begomovirus* and *Mastrevirus* (subfamily *Geminialphasatellitinae*). Currently, the subfamily *Geminialphasatellitinae* consists of four genera (*Ageyiasatellite*, *Clecrusatellite*, *Colecusatellite*, and *Gosmusatellite*) and 43 established species (Table 3) based on genus and species demarcation thresholds of $\approx 70\%$ and $\approx 88\%$, respectively of their complete genomes. The subfamily *Nanoalphasatellitinae* is more variable with at least seven genera (*Babusatellite*, *Clostunsatellite*, *Fabenesatellite*, *Milvetsatellite*, *Mivedwarsatellite*, *Sophoyesatellite*, and *Subclovsatellite*) and 19 species (Table 3) using complete genome genus and species demarcation thresholds of $\approx 67\%$ and $\approx 80\%$, respectively. Collectively referred to as alphasatellites, these plant-infecting molecules resemble the DNA-R component of nanoviruses in that they encode a replication-associated protein (Rep) and are capable of autonomous replication in host cells. They also possess a stem-loop region containing the nonanucleotide TAA/GTATTAC. However, they depend on their ssDNA HVs for encapsidation, movement, and insect transmission. The specific role of alphasatellites in the pathogenesis of their HV is unclear but some published studies have implicated their co-infections in reduced or exacerbated symptoms of the HV, reduced titer of the HV or betasatellite, or suppression of host defenses based on RNA interference.

Category 6b: Satellite ssDNA (family *Tolecusatellitidae*; genera *Betasatellite* and *Deltasatellite*)

Different satellite ssDNAs have been classified under the family *Tolecusatellitidae* with two genera (*Betasatellite* and *Deltasatellite*) based on their nt sequences. Like members of the *Geminialphasatellitinae* subfamily, the circular ssDNA molecules of betasatellites are about half the sizes (≈ 1.3 kb) of their helper Old World monopartite begomoviruses, possess a stem-loop region containing the nonanucleotide TAATATTAC, and code for a single ORF (β C1), whose product has been shown to function as a pathogenicity determinant and suppressor of host gene silencing. Deltasatellites, however, are usually about one quarter (≈ 0.7 kb) of the size of the genome of their monopartite Old World begomoviruses and bipartite New World begomoviruses. Unlike other geminivirus-associated satellite ssDNA molecules, deltasatellites do not encode for any protein. Consequently, like betasatellites, they also rely on their HV for encapsidation, replication, movement, and vector transmission. Whereas betasatellites are known to enhance the virulence of the helper begomovirus and may be essential for the maintenance of disease in the field, deltasatellites may cause a reduction on begomovirus accumulation and/or symptom severity in certain satellites-virus-host interactions. Current species demarcation thresholds within the family stands at $<91\%$ complete nt sequence identity for both genera, leading to the recognition of 61 betasatellite and 11 deltasatellite species (Table 3).

Category 7: Satellite dsRNAs

Most of the satellite dsRNAs (Table 4) occur in association with viruses in the families *Totiviridae* and *Partitiviridae*, on which they depend for the encapsidation and replication of their 0.5–1.8 kbp genomes. The totivirus-associated satellite dsRNAs encode a secreted protein toxin (the killer toxin) that is lethal to virus-free sensitive cells and to the HV that lacks the satellite dsRNA molecule. In turn, the HV that carry the toxin-encoding satellite dsRNA has immunity to that toxin; thus, the satellite dsRNA confers ecological advantage to its HV by killing competing virus- or satellite-free fungi. Unlike their *Totiviridae* counterparts, the satellite dsRNAs associated with partitiviruses do not code for functional proteins and their biological significance is not known.

Category 8a: Large linear satellite ssRNAs

Members of the large linear satellite ssRNAs have messenger RNA properties. They range in size between 0.8 and 1.5 kb and encode a nonstructural protein that may be essential for satellite RNA multiplication. All but two of the currently listed members are satellites of viruses in the family *Secoviridae*, the exceptions being bamboo mosaic virus (BaMV) satellite RNA and BNYVV RNA5 that are associated with a potyvirus and a benyvirus, respectively (Table 4). Several members of the *Secoviridae*-associated large linear satellite ssRNAs have been studied. They share 5' and 3' structural features of the gRNAs of the HV (a 3' terminal poly(A) sequence and a 5' terminal VPg). The encoded non-structural protein of different satellite RNAs are basic proteins of 36–48 kDa. For the satellite RNAs of tomato black ring virus, grapevine fanleaf virus, and Arabis mosaic virus (ArMV) (all three: genus *Nepovirus*, family *Secoviridae*), it has been shown that the encoded proteins are needed for the replication of the satellite RNA. Most large satellite RNAs of nepoviruses do not seem to have an effect on the accumulation or pathogenicity of the HV. However, this may depend on the experimental system, as the large satellite RNA of ArMV was shown to modulate the symptoms of the HV depending on the species of host plant. The BaMV satellite RNA is the only member that is encapsidated into rod-shaped particles. It encodes a 20 kDa protein that is expressed *in vivo* but is not needed for satellite RNA replication. The presence of BaMV satellite RNA significantly reduces the accumulation of the HV's gRNA. Cis-acting sequences required for BaMV satellite RNA replication have been mapped at the 5' NTR and comprise a stem-loop structure that is conserved among BaMV satellite RNA variants. The BNYVV RNA5 encode a protein of 26 kDa, which is responsible for intensification of the rhizomania disease induced by infection of BNYVV RNAs 1 and 2, plus its two satellite-like RNAs 3 and 4.

Category 8b: Small linear satellite ssRNAs

The group consists of small (<0.7 kb), linear satellite RNA molecules that are associated with plant-infecting HVs in the families *Tombusviridae*, *Bromoviridae*, and the genus *Umbravirus* (Table 4). Some of the *Umbravirus*-associated members such as groundnut rosette virus satellite RNA and tobacco bushy top virus satellite RNA may be regarded as satellite-like RNAs due to their

^assDNA, single-stranded DNA.

essential roles as components of disease complexes. Although they do not encode functional proteins, some members can attenuate or exacerbate the symptoms induced by HV infection.

Category 8c: Small circular satellite ssRNAs

Members have small (0.35 kb) genomes that may be present in both circular and linear forms in infected cells. They include satellite RNAs associated with viruses in the plant virus families *Secoviridae*, *Luteoviridae*, and *Solemoviridae*; and possibly a viroid-like satellite RNA (Table 4). There is no mRNA activity associated with these various satellite RNAs, and they all have a high degree of secondary structure. The satellite RNAs either have no effect on (*Solemoviridae*-associated satellites) or reduce the accumulation of (*Secoviridae*- and *Luteoviridae*-associated satellites) their HV.

Category 8d: Hepadnavirus-associated satellite-like RNAs (genus *Deltavirus*)

Hepatitis delta virus (HDV, unassigned genus *Deltavirus*) is a subviral agent of the human pathogen, hepatitis B virus (HBV, genus *Orthohepadnavirus*, family *Hepadnaviridae*). HDV is replicated in the nucleus by the host DNA-dependent RNA polymerase II, but is dependent upon the envelope proteins of HBV for its encapsidation and transmission, and is thus not a satellite. The HDV RNA (1679 nt) folds into an unbranched rod-like structure similar to that of viroids, and in common with the circular ssRNA satellites, contains ribozymes that are involved in the processing and maturation of this RNA during replication. The HDV RNA encodes two forms of a protein designated the delta antigen (δ Ag). The smaller, 22 kDa form (δ Ag-S), which is a nuclear phosphoprotein, is required for replication of HDV RNA, while the 24 kDa larger form (δ Ag-L), which contains an additional 19 aa at the C-terminus and is produced late in infection, is required along with δ Ag-S for assembly of the HDV RNA into HBV envelope particles. δ Ag-L also acts as an inhibitor of HDV replication. HDV intensifies the severity of liver disease caused by HBV.

Category 8e: Polerovirus-associated RNAs

Some isolates of three poleroviruses (genus *Polerovirus*, family *Luteoviridae*), *Beet western yellows virus*, carrot red leaf virus (CRLV), and *Tobacco vein distorting virus* were found to have associated with them additional RNAs of size 2.8–3 kb. These associated RNAs encoded their own viral replicases and are thus capable of autonomous replication. However, they each depend on their respective helper poleroviruses for movement, encapsidation, and transmission. Some members, such as CRLV-associated RNA, contribute to the disease caused by their HV.

Replication and Structure

Satellite RNAs

A general property of satellite RNAs is that their replication depends on the replication machinery of the HV, which involves virus- and host-encoded factors. Hence, replication of satellite RNAs depends on interactions with both the HV and the host plant. Satellite RNAs may or may not share structural features at their 5' and 3' termini in common with the HV RNA. For instance, the large satellite RNAs of the nepoviruses have an HV-encoded VPg at the 5' end and a poly(A) tail at the 3' end, as do their HV RNAs, but the satellite RNAs of cucumber mosaic virus (CMV) have a 5' cap structure, as do the CMV RNAs. But unlike the HV, the satellite RNAs do not have a tRNA-like structure that can be validated at the 3' end. Structural differences and, often, differences in the replication process between the satellite RNA and the HV RNA, indicate that the replication machinery of the HV may need to

Table 4 Classification of satellites RNA nucleic acids

Category/Species and Tentative Species	Type isolate ^a accession #	Genome/Host types ^b	Helper virus genus
7. Satellite dsRNAs			
Bombyx mori cypovirus 1 satellite RNA	AB183384	dsRNA/Fungi	Cypovirus

be adapted to replicate the satellite RNA, in ways which are not completely understood. The HV replication complex could be modified by satellite-encoded factors, as has been hypothesized for the large satellite RNAs of nepoviruses, or by unidentified host factors. In the best characterized systems, the efficiency of replication depends on the host plant. For CMV satellite RNAs, replication efficiency also depends on the strain of HV. Similarly, while the expression of the HV RNA-dependent RNA polymerase was enough for the replication of cereal yellow dwarf virus (CYDV) satellite RNA in the homologous host, this was not the case for Cymbidium mosaic virus satellite RNA in a heterologous host system, in which, however, a diRNA was amplified.

Replication has been studied best in the small noncoding satellite RNAs. For the small linear satellite RNAs of TCV and CMV, multimeric forms of both positive (arbitrarily defined as the encapsidated sense) and negative sense are found in infected tissues. The junction between monomers can be perfect or have deletions. Circular forms are not found, and replication does not proceed through a rolling-circle mechanism. Regulatory sequences for RNA replication have been mapped in detail in the satellite RNAs of TCV. In the hybrid satC molecule, a hairpin structure is a replication enhancer and has a role in depressing the accumulation of the HV. Also, structural motifs favoring recombination have been analyzed extensively in satD and satC of TCV.

The replication of small, circular satellite RNAs is by a rolling-circle mechanism; upon infection, linear, multimeric forms of the negative strand are synthesized. The multimeric plus strand is then synthesized on this template or on negative strand circular monomers, depending on the satellite RNA. The positive strand multimer is cleaved autocatalytically and ligation occurs for those satellite RNAs that are encapsidated as a circular form. Hammerhead and hairpin ribozyme structures are found in these satellite RNAs monomers or dimers, which catalyze hydrolysis or hydrolysis and ligation, respectively. Other structures required for replication and encapsidation have been mapped in CYDV satellite RNA.

Structural analyses have been done mostly with small satellite RNAs. Models for the *in vitro* secondary structure have been proposed for several satellite RNAs (CMV satellite RNA, TCV satellite RNA, TRSV satellite RNA, and CYDV satellite RNA) based on nuclease sensitivity and chemical modification of bases data. For CMV satellite RNA, *in vivo* models have also been proposed. All analyzed satellite RNAs have a high degree of secondary structure, with more than 50% and up to 70% of bases involved in pairing. The high degree of secondary structure could explain the high stability of these molecules as well as the very high infectivity reported for some of them, such as CMV satellite RNA and TCV satellite RNA. The high degree of secondary structure may also be related to their biological activity, which for these noncoding molecules must depend on structural features. As has been detailed in other sections, sequences, structural domains, and tertiary interactions involved in pathogenicity and replication have been well characterized for some small satellite RNAs.

Satellite DNAs

The replication of satellite ssDNA mimics that of the HV. Unlike RNA viruses, geminiviruses do not encode a polymerase and depend on host DNA polymerases for replication. The only geminivirus-encoded protein essential for replication is Rep. Satellite DNAs utilize the HV Rep and contain the conserved sequence for DNA nicking by the Rep. Replication takes place by a combination of rolling circle and recombination dependent mechanisms and the DNA is encapsidated in the HV virion. The replication is independent of β C1 expression. Sequence comparisons at the nucleotide and aa levels reveal several conserved structural features, despite a significant level of sequence divergence. These include an A-rich region, a sequence of about 80 nt referred to as the satellite conserved region, and putative stem-loop structure containing a mononucleotide motif, also present in geminivirus genomes.

Sequence Variation and Evolution

Sequence variation and evolution has been analyzed most for CMV satellite RNA. Early experiments under controlled conditions showed a high variability and genetic plasticity. Populations started from cDNA clones rapidly evolved to a swarm of sequences whose master sequence changed upon passage on different hosts. Analysis of genetic variants from natural populations showed again a high diversity for CMV satellite RNA. In natural populations, satellite RNA diversification and evolution proceeded by mutation accumulation and by recombination. Constraints to genetic variation were analyzed, and were related to the maintenance of base pairing in secondary structure elements. Population diversity of CMV satellite RNA was higher than for the HV, and the population structures of CMV and the satellite RNA were not correlated. These analyses also showed that CMV satellite RNA behaved in nature as a molecular hyperparasite spreading epidemically on the CMV populations. The incidence of CMV satellite RNA in CMV populations has been shown to be low, except during episodes of epidemics of tomato necrosis. High diversity of natural populations has also been shown for panicum mosaic satellite virus RNA and for BaMV satellite RNA. For BaMV satellite RNA, the diversity was highest in the NTRs. Conversely, the population of rice yellow mottle virus satellite RNAs across sub-Saharan Africa showed little sequence diversity. The incidence of these three satellite RNAs in the analyzed populations of the respective HV was, in all cases, high.

Phylogenetic analyses divide geminivirus-related satellites broadly into two categories, those isolated from host plants of the family Malvaceae and the rest isolated from other plants, mostly in the Solanaceae. Compared to satellite RNAs, satellite DNAs do not exhibit a wide diversity. They are structurally similar and lack strict specificity for HV species. Geminivirus-related satellite DNA sequences analyzed exhibit a minimum overall similarity of about 47% and 37%, at the nt level and aa level, respectively.

There has been much speculation on the origin of satellite RNAs. For CMV satellite RNA and TCV satellite RNA, it has been suggested that they could have been generated out of small sequences synthesized upon the HV RNA as a template by the HV

polymerase. This hypothesis is no longer sustained since attempts to locate the sequences with significant similarity to satellite RNA in the genomes of hosts, HVs and vectors have in general been unsuccessful. Whatever the mechanism of generation of the satellite RNAs, it seems that the satellitism as a phenomenon, that is, the dependence on a certain virus for replication, has evolved independently several times. This is suggested by the lack of correlation between satellite and HV taxonomy, and by the existence of subviral nucleic acids with different degrees of dependence on an HV. For instance, an evolutionary line from nondependent viruses to satellites such as BaMV satellite RNA through satellite viruses could have proceeded by size and information content reduction. A phylogenetic relationship between viroids and small circular satellite RNAs has also been proposed.

Expression of Foreign Sequences From Satellite Vectors

The satellite RNAs of BaMV and BNYVV, as well as the satellite DNA of tomato yellow leaf curl China virus isolate Y10 (TYLCCNV-Y10), all of which express proteins not required for the replication or spread of the satellite or HV, have been used as expression vectors of foreign sequences. In the case of the satellite RNA of BaMV, the expression of such sequences and the accumulation of the satellite RNA were reduced considerably in systemically infected leaves. Nevertheless, this satellite expression system has been useful for studying cis- and trans-acting replication signals. The 26 kDa protein encoded by RNA5 of BNYVV has been replaced with the sequence encoding the green fluorescent protein, which was expressed in both the inoculated leaves and systemically infected leaves. The small size of the satellite DNA of TYLCCNV-Y10 precludes use of this system for expression of most genes, but the system has been used to express plant gene segments inducing RNA silencing in several plants species. The STMSV system also has been used to express plant gene sequences, in place of its CP, resulting in RNA silencing of those plant genes, but not of the satellite virus or its HV. The modified STMSV expression vector was able to spread through the plant in the absence of its CP.

Satellite-Mediated Control of Viruses

The ability of some satellite RNAs to interfere with the replication of, and attenuate the symptoms induced by, their HV has been exploited to develop strategies for disease control. Two prophylactic strategies have been employed for this biocontrol approach. In the first strategy (cross-protection), the target plants are pre-inoculated with a combination of the satellite RNA and a mild strain of its HV to “vaccinate” the plant against a virulent strain of the HV. The second strategy utilizes the transgenic approach wherein the satellite RNA have been expressed in transgenic plants to provide either resistance to infection by the respective HV, or tolerance to the disease induced by the HV and/or related pathogenic satellites. Multiple mechanisms like competition for viral replicase, gene silencing and possibly other immune actions of the host may be involved in resistance. A recent study evaluated the effects of post-inoculation with CMV satellite RNA on symptoms derived from pre-infection by its HV and demonstrated that this new therapeutic strategy could be useful for combating plant viruses using properly timed treatment with attenuation satellite RNAs.

Glossary

Affimers Small proteins that mimic antibodies.
Argonaute 1 Member of the Argonaute family of proteins involved in RNA silencing and a component of the RNA-induced silencing complex.
Glutamic protease A proteolytic enzyme that contains a glutamic acid residue within the active site.
Internal ribosomal entry site An RNA element that facilitates cap-independent translation.
Satellite RNA RNA that depends on the helper virus for replication and encapsidation, and can in some cases modulate symptoms.

Viral protein genome-linked A protein covalently attached to the 5' end of positive strand viral RNA and acting as a primer during RNA synthesis.
Virus re-assortment The mixing of the genome segments of a virus into new combinations.
Virus replication complexes Intracellular complexes formed by association with intracellular membranes that are sites for stages in the replication cycle of a virus.
 β -barrel Beta-sheet composed of tandem repeats forming a closed structure.

Introduction

Secoviruses are the plant-infecting members of the taxonomic order *Picornavirales*, a group of viruses that includes more broadly known members such as poliovirus, rhinovirus and foot-and-mouth disease virus. Symptoms of Grapevine fanleaf virus (GFLV) were some of the first to be described independently across a number of European countries at the end of the nineteenth century. In the early 1960s the plant virus group to which GFLV belongs, the nematode-transmissible nepoviruses, was one of the first to be recognized, followed by, in subsequent decades, the related comovirus and fabavirus groups. Unlike all other members of the *Picornavirales* order which contain their genetic information on one positive sense strand of RNA (monopartite), the comoviruses, fabaviruses and nepoviruses are segmented, meaning they have their genome split in two. This organization is typical for the vast majority of secoviruses that have been characterized so far. However, members of the sequivirus and waikavirus groups – the latter represented by the type member Rice tungro spherical virus (RTSV), a causal component of the eponymous disease that devastated South East Asia in the 1960s and 70s – are the exceptions with an unsegmented monopartite genome.

The secoviruses, like all members of the *Picornavirales* have a number of common features. Their genomic segments produce polyproteins (contiguous clusters of functional domains) which are proteolytically cleaved into smaller functional proteins by a virus protease which is encoded within a commonly conserved helicase-protease-polymerase replication block. They are all predicted to encode a small protein (VPg) that binds to the 5' end of their genome. Virus particles are non-enveloped and approximately 30 nm in diameter. The structure of Cowpea mosaic virus, one of the frontrunners in the development of nanobiotechnological tools, is particularly well-characterized.

Since the 2000s, exceptions to the general rule that genomic RNA segments encode single polyproteins within the *Picornavirales* order have been identified. For secoviruses, evidence has come with the emergence and characterization of the torradoviruses which are apparently bicistronic for one of their genome segments, encoding a predicted protein of as yet unknown function. Another exception to assumed commonalities has been the recent discovery that Strawberry mottle virus (SMoV) encodes for a glutamic protease, in addition to the 3C-like protease conserved across all other secoviruses. The former protease is the first of its kind reported for any positive single stranded RNA virus.

Taxonomy, Phylogeny, and Evolution

The International Committee for the Taxonomy of Viruses (ICTV) (see “Relevant Websites section”) lists specific demarcation criteria for the recognition of taxa which are to be used as guidelines on a case-by-case basis for determining taxonomies.

The family *Secoviridae*, is classified within the *Picornavirales* order (a name derived from fusing pico meaning ‘small’ prefixed to ‘RNA’), a group of viruses which encode their genome on single stranded positive sense RNA. The *Secoviridae* is the only plant-infecting member of this group. Other family members (along with host and typical species) include; *Dicistroviridae* (arthropods – Cricket paralysis virus), *Iflaviridae* (arthropods – Infectious flacherie virus), *Marnaviridae* (algae – *Heterosigma akashiwo* RNA virus), *Picornaviridae* (vertebrates – Enterovirus C), *Polycipiviridae* (arthropods – *Solenopsis invicta* virus 2). There are also two floating genera; *Bacillarnavirus* and *Labrynavirus* infecting algae and protists, respectively.

At present, the family *Secoviridae* contains eighty-six species, eighty-one of which are grouped into eight genera. The vast majority (sixty-two) of species fall into three related genera (*Comovirus*, *Fabavirus* and *Nepovirus*) that form the subfamily *Comovirinae*. Nineteen species fall within the remaining five genera; *Cheravirus*, *Sadwavirus*, *Sequivirus*, *Torradovirus* and *Waikavirus*. There are five unassigned species *Chocolate lily virus A* (CLVA), *Black raspberry necrosis virus* (BRNV), *Dioscorea mosaic associated virus* (DMAV), *Strawberry mottle virus* (SMoV), and *Strawberry latent ringspot virus* (SLRSV). Recent taxonomical changes, not yet ratified by the ICTV, will place four of these species within the *Sadwavirus* genus leaving only SLRSV as unassigned. Absorption of these four species to the *Sadwavirus* genus was achieved through the generation of three new subgenera, *Cholivirus*, *Satsumavirus* and *Stramovirus*. The *Nepovirus* genus is usually informally split into three subgroups A, B and C depending on phylogenetic relationships (Fig. 1).

These relationships for all members of the order *Picornavirales* have been traditionally defined by a contiguous region (Pro-Pol) spanning the functional domains of the protease (Pro) and polymerase (Pol), characterized at each extreme by the amino acids CG and GDD, respectively (Fig. 2). Trees produced from alignments of other functional domains on the whole are less structured but are not incongruent with the relationships defined by Pro-Pol trees. Notably, monophyly of the genera *Sequivirus*, *Torradovirus* and *Waikavirus* has been detected for the helicase and coat protein domains.

There is substantial evidence for the modular nature of virus genomes and despite the overall lack of phylogenetic discordance across their functional domains the secoviruses possess genetic characteristics that are modular in nature as is suggested by the detection of distant, yet significantly closer affinities with functional domains of invertebrate-infecting members of the *Picornavirales* than with fellow secoviruses. The experimentally demonstrated existence of a completely novel glutamic protease encoded by SMoV, is in line with this paradigm.

For most secoviruses, functional domains have been ascribed based on their similarity in sequence to proteins of known function. Because of the differences in their hosts and modes of infection, within the order *Picornavirales*, MPs are unique to the secoviruses. For plant viruses in general MPs are believed to be ultimately host in origin, for secoviruses these origins are possibly multiple as illustrated in tomato-infecting and non-tomato-infecting torradoviruses where putative MPs have their closest similarities to either umbraviruses and bromoviruses, respectively.

Current models using comparative genomics suggest secoviruses are likely invertebrate in origin. For this to be the case there must have been one or many host-switching events (invertebrate to plant) leading to a period of *in planta* adaptation followed by virus emergence. The intimate relationship between virus, host and vector provides ample opportunity for host-switching in either direction (invertebrate to plant or plant to invertebrate) to have occurred. The mechanisms necessary for such a significant (interkingdom) evolutionary step to occur are still to be discovered, but unlike members of other virus families (e.g., *Reoviridae*, *Bunyaviridae*) which replicate in both plant and vector, the secoviruses have apparently lost their capacity to infect the latter.

Attempts to establish when members of the *Secoviridae* might have evolved from ancestral viruses has been done using coalescent analyses on ninety-four coat protein sequences of the subfamily *Comovirinae*. An estimated time of emergence of less than a 1000 years

Fig. 1 Schematic of the taxonomic organization of the family *Secoviridae* showing typical features for each taxon. Horizontal numbers – present number of species per taxon. Vertical numbers – year taxon was recognized (irrespective of name given). Rounded rectangles (gray) – subfamily; (colored) – genera. Ellipses – subgroup groupings. Note – listed features may not apply to all members of group. * – presented subgenera organization of the *Sadwavirus* genus has yet to be ratified by the ICTV.

Fig. 2 Maximum likelihood inferred phylogenetic unrooted tree of members of the family *Secoviridae* based on an alignment of amino acid sequences of the conserved domains between the “CG” motif of the 3C-proteinase and the “GDD” motif of the polymerase (Pro-Pol region). The bar represents the genetic distance. Rounded rectangles (gray) – subfamily; (colored) – genera. For each species, the sequence of the exemplar isolate was used for the alignments (see species tables for the sequence accession numbers). Percent bootstrap values (1000 replicates) are shown at each branch node. Branches with bootstrap values below 70% were collapsed. Virus names and abbreviations are listed in [Table 1](#).

ago was calculated for the whole group with individual species emerging at various times between 50 and 250 years ago a period coinciding with an intensification in agricultural practices. Such estimates overlook possible variations in mutation rates and the birth and death of virus lineages over time. Nevertheless, this information provides a foundation to work from as computational phylogenetic methods become more sophisticated and the number of secovirus sequences deposited in the database grows.

The bipartite nature of most secoviruses is a likely adaptation from monopartite ancestors. In the virosphere those segmented viral genomes so far discovered are predominantly plant-infecting. Segmentation results in an uncoupling of the structural block of proteins from the replication-associated protein block allowing a more refined control of translation. It also facilitates genetic shuffling of each RNA to quickly produce novel combinations (reassortants) that may or may not have a selective advantage. Genome splitting might also allow for more efficient virion packaging. A bipartite version of foot and mouth disease picornavirus, produced spontaneously by multiple passages, was demonstrated to produce more stable virions than its monopartite counterpart, with presumably a longer viability outside of the cell. Nevertheless, a bipartite genome strategy means that both segments (and virions containing each segment) have to infect the same cell for successful infection, a theoretically more probable scenario for plants viruses, as their entry into the first cells of the host will be mechanically-mediated rather than receptor-mediated as for animal viruses.

Genetic mixing, whether reassortment or recombination, an important driver of evolution, requires a physical proximity of divergent viruses achieved by mixed infections which will be prolonged in perennial hosts. Evidence for the reassortment of secovirus RNA1 and 2 has been found for a raspberry isolate of Tomato ringspot virus (ToRSV) and a number of Korean isolates of Broad bean wilt virus 2 (BBWV2). Recombination is more frequently detected, at times leading to the putative emergence of new species as in the case of grapevine chrome mosaic and grapevine deformation nepoviruses.

Members of the Family

There are presently eighty-six recognized species of secoviruses distributed across eight genera, with one unassigned species SLRSV. For the majority (62) full-length genomic sequences are available including a NCBI RefSeq assembly number. For others (24) there is still no sequence information available ([Fig. 1](#); [Table 1](#)).

Table 1 List of all ICTV classified members of the *Secoviridae*, their taxonomic order, acronyms and GenBank sequence information. # Seq – number of sequences for each virus registered in NCBI Taxonomy Browser data from which a complete genome has been assembled to give a RefSeq assembly number (GCF_number). The last column to the right provides explanation if no RefSeq assembly number is available in the form of accession numbers for incomplete viral sequences or failing that, when no sequence information is available at all, the year, (in parentheses) of the species ratification by the International Committee for the Taxonomy of Viruses (ICTV)

^aBBSV acronym has been confused with BBTMV. BBSV has highest identity (65%) with RNA2 of RCMV.

^bOriginal acronym of BBTMV was TBBMV when ratified by the ICTV in 1972.

^cAccession numbers listed for chicory yellow mottle virus are satellite sequences.

^dSubgenera organization of the *Sadwavirus* genus has yet to be ratified by the ICTV.

Virion Structure

Virions are non-enveloped particles (ca. 30 nm diameter) with icosahedral symmetry ($T = 1$, pseudo $T = 3$, Fig. 3). Virions can either be RNA containing or empty. In the case of those viruses with segmented (bipartite) genomes virions can contain either RNA1 or RNA2, but not both. Thus, for successful completion of the virus infection cycle inoculum must consist of both RNA-containing particles. For bipartite viruses, virions can be grouped into three components based on their buoyant densities; the top (T) component which is empty, and the middle (M) and bottom (B) components which contain RNA2 and RNA1, respectively.

Irrespective of the number of CPs proteolytically cleaved the CP unit as a whole comprises three β -barrel domains each one containing two anti-parallel wedge-shaped β -sheets in a jelly roll fold conformation. Each sheet is made up of four β strands. The three β -barrel domains are either contained within one CP (genus *Nepovirus*) or cleaved to generate either three individual CPs each with one domain (genera *Waikavirus*, *Cheravirus*, *Sequivirus* and *Torradovirus*), or unevenly to produce a large (L) and small (S) CP with two and one domain, respectively (genera *Sadwavirus*, *Fabavirus* and *Comovirus*). The virion is formed by the assembly of 60 CP units (whether comprised of one, two or three cleaved products), and as such is said to have pseudo $T = 3$ symmetry as compared to viruses that use 180 identical CP copies to assemble virus particles with canonical $T = 3$ symmetry. Pseudo $T = 3$ symmetry is typical of all members of the *Picornavirales* and has been suggested in the case of secoviruses to be an evolutionary vestige that in animal-infecting counterparts permits improved evasion from the immune system when compared to true $T = 3$ capsids.

High resolution structures have been determined for a number of secoviruses, including Cowpea mosaic virus (CPMV), Bean pod mosaic virus (BPMV), Red clover mottle virus (RCMV) (*Comovirus*); Arabis mosaic virus (ArMV), Blackcurrant reversion virus (BRV), GFLV and Tobacco ringspot virus (TRSV) (*Nepovirus*). The existence of empty (T) particles demonstrates RNA is not required for the maintenance of virus particles, but does not preclude its involvement in assembly. Nevertheless, there appears to be some specificity to the interactions of viral RNA in the assembled particles, electron densities indicating a consensus base composition of the interacting RNA. At the three-fold axis of symmetry of the BPMV virion, viral RNA folds into a trefoil shape implying a potential function for this structure in packaging and particle assembly. More defined interacting amino acids have been identified for the CPs; in CPMV M-virions the amino acid N174 in the large CP subunit is intimately associated with and shown to be essential for genomic RNA encapsidation. Attempts to develop an *in vitro*

assembly assay, similar to other icosahedral viruses such as Cowpea chlorotic mottle virus, for CPMV which could help shed light on the mechanisms and requirements for assembly have so far proved unsuccessful due to the insolubility of the coat proteins.

Genome Organization

Whether monopartite or bipartite, the genome of secoviruses shows an overall similar organization, with two distinct blocks for replication-associated and structural functional domains. For bipartite viruses in which these blocks are segregated the adopted standard nomenclature is RNA1 and RNA2, respectively. Typically, viral proteins are expressed as large polyproteins, one per RNA, that are eventually cleaved into smaller functional mature proteins by viral encoded proteases (Fig. 4). However, comoviruses have been demonstrated to produce two different sized polyproteins from the same RNA2 ORF derived from two different initiation codons. And unlike any other genus in the family, torradoviruses are predicted to encode a protein 5' and overlapping to the longer more conserved long polyprotein containing the predicted CPs. The lengths of the 5' and 3' untranslated region vary considerably from species to species. For some viruses (nepoviruses and sadwaviruses), there is high sequence identity between RNA1 and/or RNA2 in the 5' and/or 3' untranslated regions (UTRs). For example, the 3'UTRs of Strawberry mottle virus are ca. 1150 nt long and 96% identical.

Protein domain organization, within the polyprotein(s) is similar to that of other members of the order *Picornavirales*. The structural block, which in monopartite genomes is located upstream of the replication block encodes the CP domain, upstream of which is the MP domain. The number of CP domain proteolytic derivatives that assemble to form the capsid varies from one to three depending on the genus (see Section "Virion Structure"). Upstream of the MP, nepoviruses encode a domain that is cleaved into one (2a protein in GFLV) or two (X3 and X4 proteins in ToRSV) proteins. The 2a protein fused to the green fluorescent protein of *Aequorea victoria* has been shown to associate with the replication complex assembled from RNA1-encoded proteins. The replication block contains domains with signature motifs typical of Helicases (NTP-binding domain proteins) (Hel), 3C-like protease (Pro) and RNA-dependent RNA polymerase (Pol). Between the Hel and Pro domains lies a small domain predicted to encode the VPg (viral protein genome-linked) (Fig. 4). Upstream of the Hel domain there exists for many secoviruses a divergent region encoding a predicted hydrophobic domain of unknown function. In CPMV the domain is encompassed by a single cleaved protein derivative that has been shown to affect protease activity, and thus was assigned the name of 'protease cofactor' (Co-Pro). In Tomato ringspot virus, there are two protein cleavage derivatives upstream of the Hel domain one (X2) sharing a conserved motif with the Co-Pro of CPMV.

Genome sizes of secoviruses is variable; the smallest are the como- and fabaviruses (RNA1 ~5.9 kb and RNA2 3.3–4 kb), while the related nepoviruses are some of the biggest (e.g., ToRSV, RNA1 ~8.2 kb and RNA2 7.3 kb). In the latter, this size includes a long almost identical 3'UTR in both RNAs. In monopartite secoviruses the genome sizes range from 9.9 kb (sequiviruses) to 12.2 kb (RTSV). All genome segments are assumed to be 3' polyadenylated although experiments carried out on the sequivirus Parsnip yellow fleck virus (PYFV) found no evidence of a poly(A) tail. The only other fully sequenced sequivirus, Carrot necrotic dieback virus, is polyadenylated. Based on the genome organization of secoviruses and comparisons with the related animal-infecting genera (*Picornaviridae*, *Discistroviridae* and *Iflaviridae*) translation is plausibly mediated through a 5' internal ribosomal entry site (IRES), a highly structured RNA element that facilitates cap-independent translation. Experimental evidence is limited to date but the presence

Fig. 4 Genome organization of representative members of the family *Secoviridae*. Boxed depiction at top is the generic secovirus organization. Only regions that notably deviate from this for each taxon are highlighted in the structures below. Each RNA is shown with the open reading frames (ORFs) represented by boxes (not to scale). Ovals depict VPg molecules covalently attached at the 5' end of the RNAs. Poly(A) tails are represented at the 3' end of the RNAs by AAA. Black vertical lines indicate evidence of cleavage sites. Movement protein – MP, coat protein(s) – CP, Helicase NTP-binding protein – Hel, protease – Pro, RNA-dependent RNA polymerase – Pol. of a functional 5' IRES has been identified in the 5'UTR of Blackcurrant reversion virus, although sequences in the 3'UTR were also shown to be required for translation.

Properties and Functions of Gene Products

Once inside the cell the viral RNA can function as a messenger RNA resulting in the translation of the viral polypeptide(s). IRES have been identified for a number of members of the *Picornavirales*. The only experimental evidence for a putative IRES in secoviruses comes from Blackcurrant reversion virus for which both a candidate stem-loop (SL) in the 5' leader sequence, a cap-independent translation enhancer (CITE) at the 3'UTR and a potential kissing-loop interaction between them have been identified. Concordant with this translational model, mutational analyses of nucleotide stretches in the 5'UTR of BRV complementary to the 18S rRNA imply a potential recruitment of the 40S ribosomal subunit (Fig. 5) at the leader sequence. Similar conserved 5'UTR sequence stretches complementary to the 18S rRNA have been found for a number of other nepoviruses.

After translation, cleavage by the 3C protease (encoded on RNA1 in bipartite viruses) of the polyprotein into mature functional proteins occurs. Although cleavage site specificity of the protease varies across genera, the mechanism involved is assumed to be the same; an amino acid in the substrate-binding pocket of the protease interacts directly with the amino acid directly upstream and flanking the cleavage site. Although structurally similar to serine proteases the catalytic amino acid of secovirus proteases is a cysteine (C) – except in the Pro of Blueberry latent spherical virus for which it is a serine (S). Specificity of 3C proteases depends on the substrate binding pocket which for the majority of secoviruses is a histidine (H), but can be a leucine (nepovirus subgroups A

Fig. 5 Proposed model describing the possible mechanisms of translation for BRV RNAs. Step 1, the 40S ribosomal subunit (small oval) is recruited to the 5' untranslated region (UTR) internal ribosomal entry site (IRES), with base pairing between plant 18S rRNA and the corresponding complementary sequences of the BRV 5' leader (two small gray boxes). Step 2, after the start codon recognition, the 60S ribosomal subunit (large oval) joins to form the 80S initiation complex. Step 3, during translation elongation, the polypeptide (thin curly line) is synthesized. Step 4, after translation termination, the 80S complex is disassembled and the polypeptide is released. Step 5, long distance RNA-RNA base pairing between the 5' SL of the BRV 5' leader and the SL-1 of the 3'UTR holds two mRNA ends in close proximity, facilitating recycling of the ribosomal subunits again to the 5'UTR. An alternative mode of mRNA circularization could involve an interaction (double-headed arrow) of the poly(A)-binding protein (PABP; gray ovals) with a yet unidentified factor X, which in turn interacts (directly or through other factors) with the 5'UTR. Curved box – open reading frame (ORF); thick lines, UTRs; (A)_n – poly(A) tail. From Karetnikov, A., Lehto, K., 2008. Translation mechanisms involving long-distance base pairing interactions between the 5' and 3' non-translated regions and internal ribosomal entry are conserved for both genomic RNAs of Blackcurrant reversion nepovirus. *Virology* 371, 292–308.

and B and PYFV) or valine (Stocky prune virus, TRSV). When the binding pocket contains an H the cleavage site is typically, though not always, a glutamine (Q). The efficiency of cleavage depends on the cleavage site composition itself, the context of the amino acids flanking the cleavage site and the overall protein conformation, thus allowing for the existence of proteolytically intermediate products with functions different to that of their individual components. For example, in nepoviruses the structural block polypeptide derived from RNA2 is less efficiently cleaved by the VPg-Pro intermediate than by the fully released and mature Pro implying a possible mechanism for sequential processing and maturation of the individual functional domains in line with the infection cycle. In addition to viral protein maturation the secovirus Pro may also interact with and cleave host translation factors as has been demonstrated for the Pro of picornaviruses.

Once the main replication associated proteins (Pol, Hel and VPg) are functional, replication of the virus genome can occur within virus replication complexes (VRC) (see next section). The Hel domain, because of homology to known RNA helicases is assumed to be involved in binding and unwinding double stranded RNA structures that may form during replication. By analogy with picornaviruses the VPg is essential for viral replication acting as a primer for RNA synthesis but it may be removed from virion RNA by a host component (similar to the poliovirus unlinking enzyme). VPg is also absent on viral mRNA undergoing translation and has no effect on the infectivity of naked RNA. In nepoviruses full maturation of the Pro would shift proteolysis of the viral polypeptide and its intermediates to releasing the structural functional domains (CP and MP) of RNA2 both of which are required for virus movement. In the unique case of the newly proposed subgenus *Stramovirus* full release of the CP would also require proteolytic removal of the downstream glutamic protease.

There is plenty of evidence to suggest secoviruses move cell-to-cell in the form of virions (rather than ribonucleoproteins), como- and nepoviral MPs having been shown to be a component of tubular structures that act as a conduit for virions passing through the cell wall. Besides having an ultimate role in RNA encapsidation, some CP(s) also function as suppressors of gene silencing. Although not as potent as other classic plant virus silencing repressors (VSR) in that it does not prevent targeted mRNA degradation by the plant silencing machinery the CP of ToRSV has been shown to interact with AGO1 and relieve a translation repression mechanism. VSR activity has also been demonstrated for the small CP (CP-S) of CPMV and the smallest CP (Vp20) of Apple latent spherical virus (ALS).

Replication and Propagation

Purified total viral RNA is highly infectious but for viruses with a bipartite genome, neither RNA species by itself can infect plants systemically. RNA1 encodes for the replication-associated protein block and this is able to replicate in individual cells, but can neither move cell-to-cell or assemble into virus particles without the complementary functions of those proteins present on RNA2.

Replication occurs in VRCs, intracellular complexes formed by association with intracellular membranes. For como- and nepoviruses the Hel domain and upstream encoded proteins have been shown to interact with the endoplasmic reticulum (ER). Replication is reduced upon treatment with an inhibitor of type II fatty acid synthase, an observation that suggests VRC proliferation is not a simple reorganization of existing intracellular membranes. The Hel protein and the protein directly upstream of the Hel (Co-Pro in CPMV and X2 in ToRSV) are implicated in the accumulation of VRCs. In CPMV, VRCs in the form of irregularly shaped vesicles develop first in the cytoplasm and then coalesce around the nucleus. Electron tomography of picornavirus VRCs shows structures that during the exponential phase of infection are predominantly closed smooth single-membrane tubules that as infection progresses develop into double-membrane multilamellar structures. The ToRSV X2, Hel and Hel-VPg fusion protein and the CPMV Co-Pro and Hel-VPg fusion protein associate with the ER while other RNA1 derived mature proteins (VPg, Pro, and Pol) are soluble when expressed ectopically and are only peripherally associated with the VRCs in infected cells. This localization can be explained by the predicted hydrophobicity of the X2 and Co-Pro and equivalent domains in other secoviruses. Both molecules have predicted transmembrane helices and an amphipathic helix suggesting they may act as membrane anchors in the VRC. How viral RNA is recruited to the VRC in the first place is still unclear but replication and translation of RNA1 are tightly linked. Consistent with other virus replication-associated proteins, BPMV infection RNA1 derived proteins are exclusively *cis*-acting supporting the notion of a tight spatial molecular relationship. The RNA2 derived N-terminal proteins of BPMV (p58) and GFLV (2A) also function in *cis* and potentially serve to recruit RNA2 to the VRC.

Transmission, Host Range

In nature the majority of secoviruses are transmitted in a specific manner by insects or nematodes. Some (e.g., nepoviruses, cheraviruses, Satsuma dwarf virus (SDV), SLRSV) can be transmitted by seed and/or pollen. For members of the subgroup *Comovirinae* there is some predictability between the virus species within a genus and the vector (e.g., nepoviruses-nematodes, comoviruses-beetles, fabaviruses-aphids), while for other genera vector-virus relationships are more variable. For example, the torradoviruses; Tomato torrado virus (ToTV) and Tomato marchitez virus (ToMarV) are transmitted by whitefly species in a semi-persistent manner. However, detectable spread (horizontal transmission) of Carrot torradovirus 1 (CaTV1) and Lettuce necrotic leaf curl virus (LNLCV) in regions where whitefly numbers are limited (United Kingdom and Netherlands, respectively) has led researchers to identify aphid species as the most likely vectors. The type species of the *Cheravirus* genus Cherry rasp leaf virus (CRLV), is transmitted by the nematode *Xiphinema americanum* in the field and also through seeds, whereas ALSV has no known vector; transmission through seed and via pollen from infected apple trees occurring at a rate of 4.4% and 0.4%, respectively.

Such is the relationship sometimes between virus and their vector that their names have become intertwined, as in the case of nepoviruses and nematodes – nematode-transmitted viruses with polyhedral particles. This relationship can be very specific, exemplified by GFLV, for which a single amino acid change (Gly297Asp) on a surface loop of the CP is sufficient to significantly reduce efficiency of transmission by its only known vector *Xiphinema index*. This mutation does not seem to alter virion structure but has been proposed to inhibit the physical interaction between virus and the nematode vector receptor(s) necessary for successful transmission. However, broader nepovirus-vector relationships do exist: TRSV and ToRSV are known to be vectored by at least five nematode species; and BRV, consistent with its serological uniqueness, is transmitted by the eriophyid gall mite *Cecidophyes ribis*.

In some rare cases, secoviruses assist in the transmission of other viruses. Rice tungro, a disease that has periodically hit rice production in South East Asia is found associated with two distinct viruses; RTSV and Rice tungro bacilliform virus (RTBV) from the family *Caulimoviridae*. RTSV is transmitted by the leafhopper *Nephotettix virescens* but causes mild to no symptoms. RTBV is the main causal agent of the disease but depends on RTSV for transmission. Similarly, another waikavirus, Anthriscus yellows acts a helper virus in the aphid transmission of PYFV.

Secoviruses can either have broad or narrow host ranges, infecting predominantly dicotyledonous plants. Most nepoviruses and fabaviruses have wide host ranges, while comovirus infection is limited to a few species in the family *Leguminosae*. The whitefly transmissible ToTV, initially considered limited in host range to tomato, has been detected in over twenty weed species from eight families. SDV and related viruses have no known vector and natural infection appears restricted to species of citrus via grafting and mechanical transmission. Nevertheless, experimentally SDV has been shown to have a potentially broad host range infecting cowpea, cucumber, sesame and tobacco in a strain specific manner.

A small number of secoviruses (some nepoviruses and Strawberry latent ringspot virus) are found associated with a satellite RNA (satRNA); RNA that depends on the helper virus for replication and encapsidation, and can in some cases modulate symptoms. TRSV satellite RNA was the first satRNA ever described, and consists like other satRNAs in its class of a small (200–500 nt) RNA molecule lacking a functional open reading frame (ORF), an attached VPg and a poly(A)tail. In contrast, the other class of secoviral satRNAs are larger (1.1–1.5 kb), polyadenylated and associated with a 5' terminus VPg, and encode a protein essential for replication. Sequence similarities between different satRNAs is very limited although the predicted ORF of the large satRNAs show some structural similarities indicative of a shared function.

Epidemiology and Control

Dispersal of viruses occurs either through the infected host or the vector. In the past, plant virus spread would be local and limited to where virus and vector coincided geographically. In the wake of human globalization, virus movement across continents has

accelerated; for example, human beings are likely responsible for the present global distribution of GFLV and its nematode vector *X. Index*. And despite each country's legal measures to minimize the introduction of new plant materials the implementation of up-to-date certification schemes is essential in the monitoring and mitigation of disease outbreaks. Nematodes are slow moving, as will be the spread of any virus they vector in the field. Nevertheless, in the case of woody plants like grapevine that are cropped for multiple years, if phytosanitation practices are inadequate, virus-infected budwood can be inadvertently introduced at the very beginning of the vineyards lifetime.

Unlike nematodes; whiteflies and aphids are highly mobile and can move long distances rapidly extending the range and spread of the viruses they vector. Surveys made in the 2000s in Spain showed that ToTV was often found in mixed infections in tomato with another emerging non-whitefly-vectored potexvirus, Pepino mosaic virus (PepMV). The reason for the co-existence of both viruses has been hypothesized to be in part due to the conspicuous presence of whitefly populations for the former and a lack of genetic resistance against the latter. No increase in severity of torrado symptoms was observed in mixed infections.

In 1970s Japan a disease in rice termed *waiika* caused by infection of RTSV emerged to induce stunting and a reduction in grain quality. Generally RTSV alone causes mild symptoms but its ability to complement the transmission by leafhoppers of RTBV allowed for the emergence of tungro disease in the late 60s to mid-70s. Both viruses are transmitted in a semi-persistent manner by at least six leafhopper species that can remain viruliferous for up to a week. Inoculated plants can become sources of inoculum within one week. These conditions meant rapid spread of tungro in susceptible varieties. Attempts to control the disease has mainly alternated between the application of pesticides to reduce vector populations and the introduction of resistant varieties. Resistance principally took the form of resistance to the vector which over time broke down forcing growers to return to chemical control. In more recent years transgenic approaches that exploit RNA interference (RNAi) against both viruses have been explored along with RTSV resistance generated by CRISPR/Cas9 targeted mutagenesis of the eukaryotic translation initiation factor 4G (eIF4G).

RNAi technologies have also been applied to other nepoviruses (GFLV, ArMV, TRSV and ToRSV) mainly in herbaceous hosts, although a number of grapevine rootstocks transgenic for the CP have been developed. Constitutive expression of specific camelid-derived heavy-chain-only antibodies, or nanobodies, in *Nicotiana benthamiana* conferred strong resistance to GFLV, neutralizing the virus before cell-to-cell movement.

What control methods are employed and deployed against any plant pathogen will eventually depend on public perception of the associated risks and benefits.

Biotechnological Applications

CPMV has been at the vanguard nanobiotechnological developments and applications in part because of its high yield, simple purification and virion stability. Like other "nanotech" plant virus systems CPMV has the advantages of scalability, low-cost, low-toxicity and biodegradability. These factors, in combination with an early knowledge of its particle structure, resulted in it becoming the first plant virus to be successfully engineered to present foreign peptides on its surface with a 25 aa insertion of part of the VP1 domain of Foot and mouth disease virus (FMDV) into the β B- β C loop of the CP-S. Expression of other epitopes inserted in the β B- β C and other surface loops have also been effective, provided the insert is no greater than 40 aa with an isoelectric point (pI) of less than 9. Employing these virus-like particles (VLPs) to elicit an immunogenic response to the inserted epitope has been shown for Human rhinovirus 14, Mink enteritis virus, Human immunodeficiency virus, the bacteria *Pseudomonas aeruginosa* and *Staphylococcus aureus*, and for a number of human cancers (e.g., lung, melanoma, ovarian). The main motivation for these studies is the development of vaccines, and their stable expression in plants offers the appealing possibility of their delivery as oral vaccines provided conditions can be optimized so that CPMV VLPs tolerate the extreme physio-chemical conditions of the gastrointestinal tract long enough to be absorbed into the bloodstream. Uptake of CPMV particles into mammalian endothelial cells has been shown to be mediated by binding of the virus to the cell surface protein vimentin, a known receptor for some mammalian picornaviruses. This unexpected property could be put to use in the development of CPMV as a delivery system for medical therapeutics and imaging - RNA-containing virions of CPMV being readily fusible with a range of functional molecules.

Aside from nanotechnological applications CPMV containing vectors exploiting the hyper-translatability of a modified RNA2 5'UTR sequence have been engineered for the rapid expression of large amounts (1 g per kilogram of tissue) of pharmaceutical proteins in plants via agroinfiltration. Other secoviruses too have been cloned for biotechnological applications. In particular ALSV vectors have been used for functional genomic studies in a number of plants by means of virus-induced gene silencing (VIGS). One of the benefits of the ALSV system over other VIGS vectors is the virus' broad experimental host range which includes nightshades, cucurbits and legumes. Additionally its asymptomatic infection of most plants also means that the influence of virus infection on phenotype, as encountered with other VIGS vectors, is minimized. The ALSV system has been effectively used to "vaccinate" plants against infection from agronomically important viruses like Cucumber mosaic virus and potyviruses.

Diagnosis

One of the classical characteristics of nepovirus infection is symptom recovery, where the youngest emerging leaves of an infected plant are symptomless. Although not typical (or unique) for all nepoviruses, the cause for this recovery phenomenon has its origins in the gene silencing mechanism of the plant.

Minimizing the introduction of secoviruses into new planting material is best achieved by effective diagnostic screens and certification of seeds and propagative materials. Since the advent of molecular and serological methods diagnosis is commonly achieved by enzyme-linked immunological assays (ELISA) and/or the polymerase chain reaction. Despite its robustness, relative low cost and high throughput, ELISA or any serological method is sometimes impractical or intractable due to the technical challenges of virion purification or alternative methods of heterologous protein expression in the development of antibodies. These can be specific to each virus.

Commercial ELISA kits available for the following secovirus species – Andean potato mottle virus (APMV), ArMV, Arracacha virus B (ABV), Broad bean true mosaic virus (BBTMV), BBWV1, BBWV2, Carrot necrotic dieback virus (CNDV), CPMV, Cowpea severe mosaic virus (CPSMV), GFLV, Potato black ringspot virus (PBRV), Radish mosaic virus (RaMV), Raspberry ringspot virus (RpRSV), Squash mosaic virus (SqMV), SLRSV, Tomato black ring virus (TBRV), TRSV and ToRSV. A subset of these viruses can also be detected using commercial lateral flow devices. The utility of an interesting new technology that employs small proteins, called affimers, that mimic antibodies, has been shown to detect CPMV in crude extracts. Affimers are synthetically produced on a cystatin consensus scaffold and identified by phage display screening. Their alleged benefits over antibodies are their low cost and thermostability.

Multiplex detection methods where multiple viruses are detected in a single test are normally crop specific. Multiplex RT-PCR assays have been developed for citrus that include Satsuma dwarf viruses, and for grapevine that include ArMV and GFLV. Micro- and macro-arrays too have been employed for the multiplex detection of multiple grapevine infecting secoviruses.

With the advent of high throughput sequencing methods and their continuing drop in cost and turnover time the ability to detect multiple pathogens in multiple samples simultaneously is becoming routine and is rapidly superseding previous methodologies. Nevertheless there is a burgeoning need for “quick and dirty” tests that can be carried out by anyone anywhere. Lateral flow assays have addressed some of this need but more sensitive isothermal nucleic acid based methods like loop-mediated amplification (LAMP) and recombinase polymerase amplification (RPA) are rapidly becoming the methods of choice for point-of-use diagnostics.

Concluding Remarks

Research into secoviruses has so far provided a fascinating insight into a diverse group of viruses that share many features with their animal- and algal-infecting relatives. As human agricultural activities continue expanding and globalizing, the threat of novel disease outbreaks from existing and emergent secoviruses will remain. A clearer understanding of the biology and evolution of this group of viruses will undoubtedly better prepare us for combating their negative impact, and enlighten us as to how they and their picornavirus relatives adapt and exploit new environments and hosts. Which methods are used to control secovirus outbreaks will ultimately depend on the public's level of acceptance and perception of the associated risks and benefits. It is certainly plausible that the promise CPMV holds as a biotechnological and biomedical tool will help the secovirus name reach a broader more informed audience.

Glossary

3C-like protease Viral enzymes for polyprotein cleavage with similarity to the picornavirus 3C proteases, with similarity to chymotrypsin.

Helper component A viral-encoded protein not part of the capsid that mediates the transmission of viruses by vectors.

Monopartite Adjective describing a virus with a single particle containing a single complete genomic nucleic acid.

Polyprotein Large precursor polypeptide that is post- or co-translationally cleaved into mature protein components,

often with dynamics reflecting changing functions over time.

Semipersistent transmission A mode of vector-mediated transmission of plant viruses in which viruses are usually acquired within few minutes, and retained up to several days by vectors. Viruses do not multiply or circulate in vectors, and require no latent period between acquisition and transmission.

Synergy Co-infection of two or more viruses where disease is greater than additive and/or titer of one or more virus is enhanced.

Introduction

Viruses in the genera *Sequivirus* and *Waikavirus* are monopartite members of the family *Secoviridae*, comprising the former family *Sequiviridae*. Viruses belonging to these groups are often referred to as ‘picorna-like’ due to their similarities to picornaviruses in virion morphology and genome structure, and polyprotein expression strategy. They have monopartite single-stranded RNA (ssRNA) genomes encapsidated in isometric particles composed of three capsid proteins. They infect plants and are usually transmitted by insect vectors in nature. The genus *Waikavirus* includes pathogens of important cereal crops: Rice tungro spherical virus (RTSV), and Maize chlorotic dwarf virus (MCDV). Rice tungro disease is caused by a synergistic co-infection of RTSV with an unrelated caulimovirus, Rice tungro bacilliform virus (RTBV), and impacts rice production in South and South-East Asia. Maize chlorotic dwarf disease has been problematic in the Midwest and Southeastern United States. Members of the genus *Waikavirus* with described symptomology are phloem-limited and cause stunting, yellowing, and sometimes veinal chlorosis (**Fig. 1**). The genus *Sequivirus* shares similar genome organization but is sequence-divergent from the waikaviruses and fewer members are described, with the type species being *Parsnip yellow fleck virus* (PYFV). Members of the genus *Sequivirus* cause vein yellowing, yellow flecks, mosaic, and necrosis in infected hosts, can be mechanically transmitted experimentally, and are not phloem-limited. A unique biological feature of viruses in these genera is the ability of some members to act as (waikaviruses) or require (sequiviruses) a helper virus for transmission by insect vectors.

Viruses belonging to the genus *Sequivirus* infect mesophyll and epidermal cells and are able to be transmitted by mechanical inoculation and insect vectors, while those described in the genus *Waikavirus* are limited in phloem tissue and transmitted only by insect vectors or direct mechanical inoculation to phloem, as by vascular puncture inoculation in maize. Sequiviruses are dependent on a helper virus for their transmission by insect vectors. Waikaviruses are independently transmitted by insect vectors and presumably encode a helper component in their genomes. The viruses in each genus are primarily classified on the basis of their biological and physical characteristics, but conspicuous differences are also found in their genome features. The genomes of MCDV and RTSV are approximately 12 kb and polyadenylated at the 3′ end, whereas that of PYFV is about 10 kb and lacks 3′ polyadenylation.

Classification: Taxonomy, Phylogeny, and Evolution

The family *Secoviridae* is a combination of former families *Comoviridae* and *Sequiviridae*. The family is composed of eight genera: *Sequivirus*, *Waikavirus*, *Torradovirus*, *Sadwavirus*, *Cheravirus*, *Nepovirus*, *Fabavirus*, and *Comovirus*, as well as some unassigned members

Waikaviruses: Studied but not understood. APS Features. doi:10.1094/APSFeature-2011-11. <https://www.apsnet.org/edcenter/apsnetfeatures/Pages/waikavirus.aspx>.

(Fig. 2). Most of these are bipartite viruses, but the genera *Waikavirus* and *Sequivirus* are monopartite. The 5' end of the monopartite viruses corresponds to RNA2 and the 3' end to RNA1 of bipartite family members (Fig. 3). Currently there are three species described in the genus *Sequivirus*: *Parsnip yellow fleck virus* (the type species); *Dandelion yellow mosaic virus*; and *Carrot necrotic dieback virus*, formerly named *Parsnip yellow fleck virus*, Anthriscus strain (Table 1). In the genus *Waikavirus*, four species are described: *Rice tungro spherical virus* (type species); *Maize chlorotic dwarf virus* (MCDV); *Anthriscus yellows virus* (AYV); and *Bellflower vein chlorosis virus* (BVCV; Table 1). Other putative waikaviruses have been found in deep sequencing studies, including Blackcurrant waikavirus A, Red clover associated virus 1, and Brassica napus RNA virus 1.

Sequiviruses and waikaviruses, like other members of the family *Secoviridae*, share properties of plant picorna-like viruses, and are classified in the order *Picornavirales*. Comparison of amino acid sequences revealed that the sequence identity of the MCDV (isolate TN) polyprotein to those of RTSV (strain A) and PYFV (isolate P-121) were 51% and 35%, respectively. The NTP-binding domain in the polyprotein of MCDV (TN isolate) showed significant sequence identity to those of viruses such as RTSV (strain A, 79%), PYFV (isolate P-121, 55%), CPMV (46%), Hepatitis A virus (HAV, 47%), and Poliovirus (45%). The RdRp also shows significant similarities among members of the family *Secoviridae*. For instance, the sequence similarities in the RdRp region of MCDV (TN isolate) to those of related viruses are 75% for RTSV, 50% for PYFV, 48% for CPMV, 44% for TBRV, and 40% for HAV. Phylogenetic analysis based on the sequences of NTP-binding domains indicates that PYFV and RTSV are not noticeably similar to each other compared to their relatedness to picornaviruses and comoviruses. However, phylogenetic analysis based on the regions of RdRp suggests that PYFV and RTSV are more closely related to each other than to picornaviruses and comoviruses. The 26 kDa CP of PYFV and the 22 kDa CP of RTSV contain amino acid sequences resembling those in VP3 of Encephalomyocarditis virus and Human rhinovirus 14. Like other members of the *Secoviridae*, members of the genera *Waikavirus* and *Sequivirus* encode CPs with three jelly-roll domain in each of the 20 faces of the icosahedral virus particle. For the waika- and sequiviruses, each jellyroll domain is on a separate CP, in contrast to family members with one jellyroll domain on a small CP and two on a large CP.

Variation of Isolates and Strains

Complete sequences of sequiviruses PYFV and CNDV but not DaYMV are available. Although CNDV was formerly considered the Anthriscus strain of PYFV, strain variation in the currently classified species is not described for members of the genus *Sequivirus*. Complete sequences of the waikaviruses RTSV, MCDV, and BVCV, and putative waikaviruses Red clover associated virus 1 and Brassica napus RNA virus 1 are available, as are partial sequences of the putative member Blackcurrant virus A, but no sequences

Fig. 2 Maximum likelihood inferred phylogenetic unrooted tree of members of the family *Secoviridae* based on an alignment of amino acid sequences of the conserved domains between the “CG” motif of the 3C-proteinase and the “GDD” motif of the polymerase (Pro-Pol region). The bar represents the genetic distance. Rounded rectangles (gray) – subfamily; (colored) – genera. For each species, the sequence of the exemplar isolate was used for the alignments (see species tables for the sequence accession numbers). Percent bootstrap values (1000 replicates) are shown at each branch node. Branches with bootstrap values below 70% were collapsed. Virus names, abbreviations, and GenBank accession numbers of sequences used to create the tree are: Strawberry latent ringspot virus (SLRSV), GCF_000857165; Stocky prune virus (StPV), DQ143874 and DQ143875; Arracacha virus B (AVB), GCF_000907115; Currant latent virus (CuLV), GCF_001503195; Cherry rasp leaf virus (CRLV), GCF_000859565; Apple latent spherical virus (ALSV), GCF_000861545; Parsnip yellow fleck virus (PYFV), GCF_000862945; Carrot necrotic dieback virus (CNDV), GCF_002817415; Maize chlorotic dwarf virus (MCDV), GCF_000861445; Rice tungro spherical virus (RTSV), GCF_000860625; Bellflower vein chlorosis virus (BVCV), GCF_001308735; Squash chlorotic leaf spot virus (SCLSV), GCF_002219665; Tomato torrado virus (ToTV), GCF_000872965; Tomato marchitez virus (ToMarV), GCF_000879575; Carrot torradovirus 1 (CaTV1), GCF_000927615; Motherwort yellow mottle virus (MYMoV), GCF_002220005; Lettuce necrotic leaf curl virus (LNLGV), GCF_002219685; Strawberry mottle virus (SMoV), GCF_000850445; Black raspberry necrosis virus (BRNV), GCF_000867325; Satsuma dwarf virus (SDV), GCF_000860985; Chocolate lily virus A (CLVA), GCF_000895075; Dioscorea mosaic associated virus (DMaV), GCF_001876835; Grapevine fabavirus (GFabV), GCF_003033815; Prunus virus F (PrVF), GCF_003033845; Cucurbit mild mosaic virus (CuMMV), GCF_002867105; Broad bean wilt virus 1 (BBWV1), GCF_000853465; Broad bean wilt virus 2 (BBWV2), GCF_000861605; Gientian mosaic virus (GeMV), GCF_000880435; Cowpea severe mosaic virus (CPSMV), GCF_000861225; Squash mosaic virus (SqMV), GCF_000861625; Radish mosaic virus (RaMV), GCF_000879335; Bean pod mottle virus (BPV), GCF_000862925; Red clover mottle virus (RCMV), GCF_000860425; Cowpea mosaic virus (CPMV), GCF_000860385; Raspberry ringspot virus (RrRSV), GCF_000854425; Tomato ringspot virus (ToRSV), GCF_000860465; Cherry leaf roll virus (CLRV), GCF_000893515; Soybean latent spherical virus (SLSV), GCF_001923735; Peach rosette mosaic virus (PRMV), GCF_002029615; Blueberry latent spherical virus (BLSV), GCF_002867165; Grapevine fanleaf virus (GFLV), GCF_000860305; Arabis mosaic virus (ArMV), GCF_000855205; Cycas necrotic stunt virus (CNSV), GCF_000860925; Potato virus B (PVB), KX656670.1 and KX656671; Grapevine chrome mosaic virus (GCMV), GCF_000862025; Tomato black ring virus (TBRV), GCF_000853325; Beet ringspot virus (BRSV), GCF_000849565; Artichoke yellow ringspot virus (AYRSV), GCF_002986065; Grapevine Bulgarian latent virus (GBLV), GCF_000892035; Blackcurrant reversion virus (BRV), GCF_000860405; Tobacco ringspot virus (TRSV), GCF_000856105; Aeonium ringspot virus (AeRSV), GCF_002867145; Melon mild mottle virus (MMMoV), GCF_002867185; Mulberry mosaic leaf roll associated virus (MMLRaV), GCF_002867205. Created by Thompson, J.R. for Encyclopedia of Virology and reproduced with permission.

Fig. 3 Comparative genome organizations of PYFV, RTSV-A, MCDV-S, and BPMV. ORFs are indicated with rectangles. Horizontal lines at both ends of the ORFs represent the 5'- and 3'-UTRs of the genome. Solid vertical lines dividing the ORF correspond to the positions of verified proteolytic cleavage sites, while the positions corresponding to predicted cleavage sites are indicated with dotted lines. Nucleotide coordinates of translation start and stop codons for the polyproteins and the length of the entire genomes are indicated with numbers above the genomes. Numbers below the regions encoding CP1–CP3 are the predicted molecular weight (kDa) for the respective CP. Shaded areas represent the approximate region encoding NTP-binding domain. The regions in the ORF are shown with Hel for putative NTPase/helicase, Pro for 3C-like protease, and RdRp for RNA-dependent RNA polymerase. A(n) indicates polyadenylation.

Table 1 Virus members in the genera *Sequivirus* and *Waikavirus* in the family *Secoviridae*. Type species are written in bold fonts

Genus/virus	Acronym	Accession#	Genome size (kb)	Geographical distribution	Major natural host	Transmission vector

^aEstimated size (nucleotide sequence not reported).

are available for AYV. Multiple isolates of RTSV and MCDV have been completely sequenced and strains are described based on sequence and biological differences. Complete sequences are available for RTSV isolates RTSV-A (Philippines), Seberang Perai (Malaysia), and Vt6, a resistance-breaking Philippine isolate, and Andhra Pradesh, West Bengal, and Orissa collected in India. Nucleotide sequences of these isolates share 90%–97% identity, with Indian isolates clustering separately from isolates from the Philippines and Malaysia. Most diversity analyses for RTSV focus on the CP. Examination of nucleotide sequences of the RTSV CP revealed broad genotypic variation among and within geographic isolates, although the relationship of genotypic variation with the pathogenicity is not understood yet. CPs of isolates of RTSV from the Philippines and Malaysia show about 95% sequence similarity, while those from Bangladesh and India differ from the Philippine isolate by about 15%. The CP3 of the Indian isolate was also distinguishable from that of the Philippine isolate in electrophoretic mobility and the response to cellulolytic enzyme. Genotypic surveys on the CP sequences of RTSV field isolates collected from various sites in the Philippines and Indonesia indicated that a high degree of genetic diversity exists among the field isolates, and that infections with mixed genotypes in single sites are not uncommon. Phylogenetic analysis based on the CP sequences of the RTSV field isolate suggested that the clustering of genotypes found in Philippine sites was significantly different from that found in Indonesia sites, indicating some geographic isolation of RTSV populations. Strain Vt6 of RTSV was found to possess infectivity to some rice cultivars which the type strain A may not be able to infect. Amino acid sequence of strain Vt6 was approximately 96% identical to that of strain A, with greater dissimilarity in the leader protein region and the putative small ORF found near the 3' end.

Four isolates of MCDV have been reported. The S isolate of MCDV shares 99% nucleotide and polyprotein sequence identity to the type (T) isolate and both have bright veinal chlorosis and strong symptoms, particularly the S isolate. The sequences and origin of isolates described as S and T in earliest pre-sequencing literature are somewhat unclear, but S was probably a lab-selected subset of T collected in Ohio, and both are considered the same strain. The mild (M1) isolate exhibits very mild or no obvious symptoms by itself including no measurable stunting, but leaf texture changes and infected plant weight is reduced. M1 may develop transient severe symptoms in co-infection with S. M1 has only 61% polyprotein amino acid identity with isolate T. Antisera raised against isolate T react strongly with isolate S, but not with isolate M1. Isolate Tennessee (TN) of MCDV is also significantly divergent from isolate T, showing only 60% of amino acid sequence identity, but comparative TN symptom severity is unreported. In a survey of Ohio, where MCDV-M1 and MCDV-T isolates were first collected and identified, M1 and T sequences but no intermediate, recombinant, or divergent sequences were found. A more divergent partial MCDV sequence was identified in an Oklahoma tallgrass survey for viruses, but other MCDV isolates have yet to be identified. The low levels of amino acid sequence identity among the isolates of MCDV has raised the suggestion that they may represent distinct virus species. Within the family, species are demarcated by CP aa sequences <75% identical, Pro-Pol aa sequences <80% identical, antigenic differences, host range differences, vector specificity differences, and absence of cross-protection. MCDV-M1 CP polyprotein amino acid sequence is 85% identical to that of MCDV-TN, but only 65% identical to that of MCDV-S or MCDV-T. MCDV Pro-Pol amino acid sequences (based on RTSV-A protease start annotation) from MCDV-M1 are 80% identical to MCDV-TN, but each is only 67%–68% identical to MCDV-S or MCDV-T. Thus, MCDV-TN and MCDV-M1 meet sequence criteria for classification as a distinct species from MCDV-S or MCDV-T, but biological differences other than symptom severity have not been described.

Properties of Virions

Sequiviruses and waikaviruses have non-enveloped isometric particles approximately 30 nm in diameter (Fig. 1). The sedimentation coefficients of the virions are 153–159S for sequiviruses and 175–183S for waikaviruses. The buoyant density of PYFV virions in CsCl is 1.49 g ml⁻¹, and that of waikaviruses is 1.51–1.55 g ml⁻¹. Genome sequences and immunodetection of the viruses indicate that the virions consist of three capsid proteins (CPs). The sizes of CPs range from 22 to 35 kDa, depending on virus species and isolates. The virion of RTSV (Philippine-type strain A) consists of three proteins of 22.5 (CP1), 22 (CP2), and 33 (CP3) kDa. The predicted molecular masses for the CP of MCDV TN are 22, 23, and 31 kDa, and those of PYFV (P-121 isolate) are 22.5, 26, and 31 kDa.

Genome Organization

The genomes of sequiviruses and waikaviruses are positive-sense, monopartite ssRNA. The genome sizes range from approximately 10 kb for sequiviruses to 12 kb for waikaviruses. The genomes contain a large open reading frame (ORF) encoding a polyprotein presumably proteolytically processed by viral-encoded protease(s) during translation (Fig. 3). The large ORF in the genome of PYFV putatively encodes a polyprotein consisting of 3027 aa residues with a predicted molecular mass of about 336 kb. The large ORF in the genomes of waikaviruses encodes a polyprotein of approximately 400 kb, which has about 3440–3470 aa residues. In addition to the ORF for the polyprotein, short ORFs were also identified near the 3' and the 5' ends of MCDV and RTSV genomes. Two RNA species which seemingly correspond to sub-genomic transcripts from the short ORFs locating near the 3' end of the RTSV genome (strain A) were detected from infected plants. However, the lengths and locations of the short ORF in the genomes of waikaviruses vary considerably among viruses and isolates, and the presence of products translated from these ORFs has not been confirmed in plants. Another small ORF overlapping the N-terminal leader protein, ORFX, was identified by bioinformatic analysis. ORFX sequence is conserved across waikaviruses, but is not found in sequiviruses. ORFX expression is not experimentally

confirmed and mode of expression is not known. An AUG is present, but upstream sequence is also in frame. Waikaviruses and sequiviruses are likely to have a 5' virus-linked protein (VPg) and not a 5-methyl guanosine cap, but covalent linkage of a 5' VPg has not been demonstrated.

The 5'-untranslated region (UTR) in the genome of PYFV is about 0.28 kb in length, while those of waikaviruses are longer, about 0.43 kb in MCDV and 0.52 kb in RTSV. The 5'-UTR in the genomes of MCDV and RTSV has several AUG sequences upstream of the putative polyprotein start site, and appear to form extensive secondary structures. It is possible that such secondary structures may serve as the internal ribosomal entry site, as observed in the genomes of picornaviruses, to avoid the interference on translation by upstream AUG sequences, but no experimental evidence for this is yet available. No stable secondary structures are recognized in the 5'UTR of the PYFV genome; however, several short stretches of pyrimidines (UCUCUY) are present in the region. The 3'UTR in the genomes of waikaviruses are polyadenylated and unusually long. The length of 3'UTR in the genomes of MCDV and RTSV are approximately 1.0 and 1.2 kb, respectively, provided that the short ORFs near the 3' end of genomes are not translated. The 3'UTR in the genome of PYFV is approximately 0.5 kb in length. Unlike the genomes of waikaviruses, that of PYFV is not polyadenylated, but a part of 3'UTR is likely to form a stem-loop structure which is similar to that found in the genomes of flaviviruses.

Properties of Viral Proteins

Polyproteins of sequiviruses and waikaviruses are predicted to be cleaved into seven or more mature proteins through proteolytic maturation. Polyproteins of sequiviruses and waikaviruses contain a protease region similar to the 3C cysteine protease of picornaviruses and other viral proteases resembling the 3C protease such as the 24 kb protease of family member cowpea mosaic virus (CPMV) and the Nla protease of the potyvirus tobacco etch virus. For example, considerable similarity was found between the region delimited by the aa residues 2643 and 2853 in the polyprotein of RTSV (strain A), and a region in the 24 kb protease of CPMV. RTSV protease cleavage sites are not clearly conserved in MCDV, and the sequence context is not well-defined. 3C-like protease cleavage sites are not reliably predicted, but usually cleavage occurs between a glutamine (Q) residue and a small amino acid residue (e.g., M, S, V, A, L, I, G). Possible cleavage sites within polyproteins have only been validated for a subset of mature proteins. Whether other protease activity besides the 3C-like protease is encoded by sequiviruses or waikaviruses is also not experimentally determined.

The N-terminal part of the polyprotein is highly divergent between waikaviruses and sequiviruses, and among members of the family *Secoviridae*. Within the family, proteins encoded in this position function in virus movement (e.g., Bean pod mottle virus; [Fig. 3](#)) or have unknown function. Although the predicted sizes of the putative leader proteins are about 40 kDa in PYFV and 70–78 kDa in waikaviruses, the sizes of proteins detected with the antisera specific to the putative leader proteins are significantly smaller than predicted. An antiserum specific to the putative RTSV leader protein detected a protein of about 32 kDa in extracts from infected plants. An antiserum specific to the ca. 78 kDa MCDV leader protein detected proteins with of ca. 50, 35, and 25 kDa in extracts from plants infected with MCDV-S. The MCDV 78 kDa polyprotein was demonstrated to be cleaved by the virus-encoded 3C-like protease into p51 and p27 proteins. The precursor 78 kDa protein and p51 have silencing suppressor activity. Silencing suppressor function is conserved in BVCV and other waikaviruses but appears to have variable strength in the agroinfiltration assay among the orthologs. No evidence for silencing suppressor activity or *in vitro* cleavage by the cognate viral protease was observed for the corresponding N-terminal ca. 43 kDa PYFV protein, which is sequence divergent from similarly-positioned waikavirus proteins and may not be proteolytically processed further.

A leader protein found in the polyprotein of aphthoviruses in the family *Picornaviridae* has a protease activity which cleaves itself autocatalytically from the polyprotein. It was proposed that the ca. 35 kDa protein of MCDV is generated from the leader protein region through autoproteolysis of p51 at the putative cleavage site ALVRLFHGSAE (aa residues 150–160), while p27 results from the cleavage at Q445/S446 and Q686/S687 by the viral 3C-like protease. Autocatalytic cleavage has not been experimentally demonstrated, however. The p27 product of the MCDV 78 kDa protein has been implicated as a helper component since a protein of this size was detectable in leafhoppers fed on infected plant using antiserum against the MCDV leader polyprotein, but function has not been definitively demonstrated. This postulated role of p27 is consistent with the result from a serological blocking experiment showing that the helper component is not the virion or CPs.

Three consecutive CPs are encoded after the N-terminal protein region of the sequi- and waikaviruses. Protease cleavage sites of the N-termini of CPs are defined by amino acid sequencing of purified virion proteins for PYFV, MCDV-S and MCDV-TN, and RTSV. The proteolytic cleavage sites for the RTSV CPs determined by N-terminal amino acid sequencing were mapped to Q644/A645, Q852/S853, and Q1055/D1056 for the junctions between leader protein/CP1, CP1/CP2, and CP2/CP3, respectively. Similarly, MCDV-S CP junctions were mapped to Q686/S687, Q896/L897, and Q1098/V1099 from N to C-terminus. The context of these cleavage sites suggests that the CPs are processed *in trans* by the viral 3C-like protease. However, cleavage at these sites with the RTSV protease was not detected *in vitro*. Based on N-terminal sequencing of CPs, PYFV sequenced CP junctions were mapped to S394/P395, N588/A589, and Q810/A811.

The difference in the reactivity among the CPs of RTSV with the antibody raised against the virus particles indicated that the largest 33 kDa CP (CP3) is the major antigenic determinant on the surface of particles, although the structural details of virus particles have not been elucidated yet. The size of CP3 of RTSV (Philippine isolate) in the crude extract from infected plants detected by the antibody specific to CP3 appeared to be 40–42 kDa, markedly larger than that detected from purified virus

preparation or that expected from the genome sequence. It is likely that the size of CP3 in infected cells is larger due to post-translational modification, but the modified moiety appeared to be cleaved off probably by the treatment with cellulolytic enzymes during virion purification. For MCDV, the antisera against the purified virion detects the largest two coat proteins, CP1 and CP2, most strongly, and CP3 weakly or not at all, suggesting that this coat protein is internal or less antigenic. (For MCDV, CPs are numbered by size rather than ORF location as for RTSV, and the most antigenic CPs correspond to the largest ones in both.) A slower-migrating protein was also observed with MCDV virion antisera, which was also hypothesized to be a post-translationally modified largest CP.

The central region flanked by the CPs and the protease regions in the polyproteins of viruses belonging to the family *Secoviridae* contains sequences with similarities to helicase, protease, and RNA-dependent RNA polymerase (RdRp) of picornaviruses and comoviruses. The NTP-binding domain of the central polyprotein regions shows extensive similarity to the corresponding domains in the 58 kDa protein of CPMV and the 2C proteins of picornaviruses and contains motifs GX4GKS and DD, which are conserved among proteins with NTP-binding domains. The 58 kDa protein and the 2C protein presumably function as a nucleoside triphosphatase (NTPase)/helicase required for the initiation of negative-strand RNA synthesis. Antibodies specific to protein segments from the central region of the MCDV polyprotein reacted with three protein species in extracts from infected plants, indicating that the central region containing NTP-binding and helicase domains is likely also processed into smaller proteins.

The 3C-like protease of sequi- and waikaviruses follows the central region and precedes the polymerase. Immunodetection using an antiserum raised against a protein containing the putative protease region of RTSV indicated that the size of mature protease in infected plants is approximately 35 kDa. The sequence context of cleavage sites for the 3C-like cysteine protease and the results from *in vitro* translation and autocatalytic cleavage assays from partial genomic RNA templates defined the region of the protease in the RTSV polyprotein to be from aa 2527–2852. An internal cleavage site of the RTSV protease was also identified *in vitro* in a later study, but its biological significance, if any, is not known. The RTSV protease presumably acts in *cis* to cleave itself from the adjacent protein regions, but *trans*-cleavage by the RTSV protease was also observed to occur between the protease and the putative helicase regions *in vitro*. Based on the sequence alignment among the 3C-type proteases, aa Glu2717 and Cys2811 in the RTSV polyprotein were predicted to constitute part of the catalytic triad with His2680 and His2830 as contributing residues. Substitutions of these aa abolished or drastically reduced the proteolytic activity, substantiating their important roles in the protease. These aa are conserved in the protease regions of other waikaviruses.

The C-terminal region in the polyproteins of sequi- and waikaviruses is a predicted RNA-dependent RNA polymerase (RdRp). The RdRp region of RTSV (strain A) was defined in the region between aa 2853 and 3473 with the conserved YGDD motif at aa 3270–3273. The RdRp region of MCDV (isolate TN) has the conserved YGDD motif at aa 3238–3241. In addition, motifs such as DYSXFDG (aa 3129–3135 in the MCDV polyprotein) and PSGX3TX3NS (aa 3189–3200) were identified to be conserved among the RdRp regions of MCDV, CPMV, and Tomato black ring virus (TBRV). Multiple alignment of the RdRp region of PYFV (isolate P-121) with those of CPMV, TBRV, and Poliovirus showed that they share several conserved motifs including sequences YGDD (aa 2629–2632 in the PYFV polyprotein), PSGX3TX3NS (aa 2580–2591), and FLKR (aa 2684–2687).

Transmission

Several waikaviruses exhibit transmission ‘helper’ phenomena, as observed in cow parsley infected with PYFV and the waikavirus Anthriscus yellows virus (AYV), and rice plants infected with Rice tungro bacilliform tungrovirus (RTBV) and the waikavirus RTSV. In these cases mixed infections are the outcome of a waikavirus ‘helping’ insect transmission of another virus (AYV helping PYFV or RTSV helping RTBV). Due to transmission helping, both the waikavirus and the virus it helps are also transmitted by aphid or leafhopper vectors in a semipersistent manner, and in both cases the non-waikavirus cannot otherwise be transmitted by the insect vector.

PYFV is transmitted by aphids from plants infected with both viruses or by aphids previously fed on plants infected with AYV. Aphids seem to retain PYFV and AYV for up to 4 days. Even though AYV cannot infect parsnip, PYFV can be transmitted to parsnip by aphids fed on other plants infected with AYV and PYFV. Therefore, AYV apparently acts only as the helper virus for aphids to acquire PYFV, and is not necessary for the infection process of PYFV. The name of the genus *Sequivirus* comes from the Latin word ‘*sequi*’, which means to follow or accompany, in reference to the dependent insect transmission of PYFV. Incidences of mixed infection in lettuce with dandelion yellow mosaic virus and lettuce mosaic virus were also reported, but their relationships in aphid-mediated transmission are still unclear.

Green leafhoppers (*Nephotettix* spp.) transmit RTSV and RTBV simultaneously or singly from source plants infected with both viruses. RTSV is independently transmitted by leafhoppers, but RTBV can only be transmitted by leafhoppers that have fed on plants infected with RTSV. Although leafhoppers retain RTSV for only 3–4 days, their ability to acquire and transmit RTBV may persist for up to 7 days. Neutralization of RTSV-viruliferous green leafhoppers with anti-RTSV immunoglobulin markedly reduced the ability to transmit RTSV but still retained the ability to acquire and transmit RTBV. These observations indicate that while RTSV is the helper virus for the leafhopper-mediated transmission of RTBV, the helper function is associated with factors other than RTSV virions or CP.

Evidence for a helper component in the waikavirus MCDV is based on experiments showing requirements for its own transmission, which include a component not purified with virions in membrane feeding experiments. Purified MCDV-S virions fed to

blackfaced leafhopper vectors by membrane feeding were not transmitted unless leafhoppers were previously fed on plants infected with the MCDV mild strain MCDV-M1. Leafhoppers fed on MCDV show an electron-dense “matrix” in the foreguts observed by transmission electron microscopy, which has been proposed to be composed of helper component protein. The ca. 25 kDa proteolysis product of MCDV R78 (likely p27) was postulated to be the helper component protein based on detected retention in virus-exposed leafhoppers. However, the helper component for MCDV or other waikaviruses has not yet been definitively demonstrated. For most more recently discovered members of the genera *Sequivirus* and *Waikavirus* discovered by deep sequencing, the vectors and transmission modes are not yet described.

Diseases and Management

Important diseases are described for the most-studied waika- and sequiviruses, but not known for some of the viruses identified by sequences. Major diseases caused by waikaviruses include rice tungro disease and maize chlorotic dwarf disease. Rice tungro disease is caused by the synergistic coinfection of RTSV and RTBV. Both viruses are transmitted by green leafhoppers in a semipersistent manner. RTSV alone does not cause conspicuous symptoms except occasional slight stunted growth, but severe disease results when plants are co-infected with RTSV and RTBV (Fig. 1). Such synergistic effects of RTSV on symptom development are also observed when RTSV co-infects plants with viruses such as Rice grassy stunt virus and Rice ragged stunt virus. Rice plants infected with RTBV alone exhibit symptoms such as stunted growth, yellow to yellow-orange discoloration of leaves, and reduced tillering. Severity of rice tungro disease outbreaks vary from year to year with vector populations. It is managed with vector control using insecticides or crop rotation as well as genetic resistance in rice to leafhoppers and RTSV. MCDV is present in the U.S. and is managed by removal of its overwintering host, Johnsongrass (*Sorghum halepense*) in and around fields. Other unidentified changes in cultivation practices may have contributed to its incidence reduction since the 1970s. Serological and amplification-based assays are effective for diagnostics of both RTSV and MCDV. PYFV and CNDV are pathogens of vegetable crops, with PYFV causing yellowing and mosaic of parsnip and celery, and CNDV causing mosaic, necrosis and dieback in carrot, chervil, coriander, and dill. These are managed by planting seed in areas with no virus reservoir and limited vector aphid populations.

Concluding Remarks

Waikaviruses and Sequiviruses are unique monopartite viruses that include important pathogens and have unusual molecular biology and transmission features. Only a few viruses are well-described from each genus, although additional viruses with sequences similarity continue to be identified by deep sequencing, and tools continue to add information about the biology and molecular biology of these viruses in the family *Secoviridae*.

Glossary

Icosahedral particle Spherical viral particle that is a polyhedron having 20 faces.

Leaky scanning of ribosomes Mechanism during translation initiation for escaping the first start codon, which occurs when the first AUG resides in a very poor context and therefore only some ribosomes initiate translation at that point.

Ribosomal frameshifting – 1 Event occurring during translation elongation when the ribosome shifts its frame for reading the mRNA exactly one position in the upstream direction.

Satellite RNA Subviral agent consisting of RNA that becomes packaged in protein shells made from coat protein of the helper virus and whose replication is dependent on that virus.

Introduction

Solemoviruses are plant viruses with single-stranded RNA (ssRNA) genome of positive polarity with small icosahedral virion. Some solemoviruses are distributed throughout the world; others are limited to one continent or even to one endemic region. A number of solemoviruses are the causative agents of viral diseases of important crops. Rice yellow mottle virus (RYMV) is economically the most important virus causing 20%–100% yield loss of rice production in Africa. Subterranean clover mottle virus (SCMoV) damages seriously Australian grasslands, and Papaya lethal yellowing virus (PLYV) is responsible for a severe disease in Brazilian papaya plantations.

The first isolated solemovirus was Southern bean mosaic virus (SBMV), described in 1943. It was proposed in 1969 that single-component-RNA beetle-transmitted viruses be placed into a Southern bean mosaic virus group. Since 1995, this group was recognized by the International Committee on Taxonomy of Viruses (ICTV) as the genus *Sobemovirus*, unassigned to any family. The family *Solemoviridae* was created in 2017 to group together the genera *Sobemovirus* (including 19 species) and *Polemovirus* (with only one member; [Table 1](#)). During the last years, the list of members has increased and is expected to keep growing, especially due to new available metagenomic data.

From the name Southern bean mosaic virus derives the genus name *Sobemovirus*. The name of the genus *Polemovirus* comes from polerovirus and sobemovirus to indicate the relationship of polemoviruses to those genera, as explained in the genome section.

Virion Structure

Solemovirus particles are very stable icosahedral virions of 25–34 nm in diameter displaying T=3 symmetry. The particle is built of 180 coat protein (CP) molecules (~30 kDa) that are translated from sub-genomic RNA (sgRNA). The single-stranded genomic RNA and sgRNA together with a viral genome-linked protein (VPg) are packaged inside the virion.

The three-dimensional structures of *Cocksfoot mottle virus* (CfMV), *Sesbania mosaic virus* (SeMV), *Southern cowpea mosaic virus* (SCPMV), RYMV, and *Ryegrass mottle virus* (RGMoV) virions have been determined utilizing X-ray crystallography. CP monomers are chemically identical and can adopt three different conformations (A, B, and C). The A subunits group at 5-fold axes to form 12 pentamers, while pairs of B and C subunits meet at 3-fold axes to form 20 hexamers. The combination of hexamers and pentamers gives the particle its characteristic shape. The atomic structure of SBMV particle drawn with computer graphics is shown in [Fig. 1](#) (A subunits in red, B and C in blue and green).

Fig. 1 Atomic structure of the entire virus particle of SBMV shown with computer graphics. Each subunit is shown as the C α tracing in different colors to depict the different geometric environments within the icosahedral shell. Red: Icosahedral 5-fold; Blue-Green: icosahedral 3-fold or quasi-6-fold clusters; Green at the center of the viral particle: icosahedral 2-fold. From Abad-Zapatero., G., 2002. *Crystals and Life: A Personal Journey*. International University Line, ISBN: 0-9720774-0-5. plate XVIII, with permission.

The root mean square deviations between superimposed coordinates of C α atoms of solemoviral CP residues are in general 1.4–1.5 Å. Interestingly, the virion of RGMoV is smaller and slightly more similar to the virion of Tobacco necrosis virus (family *Tombusviridae*) than to other solemovirus virions. Homology modeling of the 3D structures of the Rottboellia yellow mottle virus (RoMoV) and Artemisia virus A (ArtVA) CPs confirm with 100% confidence that they adopt the overall fold shown for the RGMoV CP and tombusvirus-like viral CPs. In addition to protein–protein and protein–RNA interactions, each icosahedral unit is stabilized by three calcium-binding sites located between subunits AB, BC, and CA. Studies with SCPMV, SeMV, and RYMV particles

demonstrate that the stability of the virions depends greatly on pH and the availability of calcium ions. Upon alkaline pH or removal of the cations, the virus particles swell and become less stable.

The primary sequences of CPs among solemoviruses are quite different. However, the three-dimensional structures are nearly identical. The CP is divided into two domains: C-terminal S (shell) domain, which has an eight-strand jellyroll β -sandwich topology, common to non-enveloped icosahedral viruses, and N-terminal R (random) domain, which is disordered in subunits A and B, but is partially structured in subunit C. The disordered beginning of R domain seems to interact with the genomic RNA in the interior of the virus particle. The S domain is the building block of the virion. The R domain is rich in basic amino acid residues and contains at its first half an arginine-rich motif (ARM). The ARM comprises a bipartite nuclear targeting signal (NLS). In the case of CfMV, abolishment of the NLS does not affect virus infectivity. Studies with SCPMV and SeMV CPs demonstrate that ARM is essential for RNA encapsidation but not for particle formation. However, the presence of RNA enhances the overall stability of capsids.

Packing of viral nucleic acid is supposed to happen when CP recognizes a specific region inside the virus genome. In the case of SCPMV, a putative stem-loop sequence within a conserved region encoding serine protease has been reported to bind CP. Nevertheless, this sequence has not been demonstrated to nucleate SCPMV assembly.

According to a number of studies, solemovirus particles assemble as follows: CP subunits with disordered amino termini form a pentamer of AB dimers. Then, ARM interacts with RNA and CC dimers are formed. More CC dimers are added and a swollen T=3 particle is built that becomes compacted when calcium ions enter the subunit interfaces.

Virion disassembly occurs when cations are removed. In the case of SBMV virions, pentamers have been suggested as exit ports for viral RNA. Particles of this virus disassemble completely after initiation of RNA translation.

In addition to the genomic and sgRNA, some solemoviruses (Lucerne transient streak virus (LTSV), *Solanum nodiflorum* mottle virus (SNMoV), SCMoV, Velvet tobacco mottle virus (VTMoV), and RYMV) encapsidate a circular viroid-like satellite RNA (satRNA). The sizes of these circular satRNAs range from 220 to 390 nt, RYMV satRNA being the smallest (220 nt) known naturally occurring circular RNA.

Genome

Solemoviral genomes are 4.0–4.6 kb in length. The polycistronic positive-sense ssRNA genome consists of five open reading frames (ORFs) in the case of sobemoviruses and four in the case of polemoviruses (Fig. 2). All ORFs, except the most 3' proximal, are expressed from the genomic template. The last ORF, encoding CP, is translated from the sgRNA.

The genomic and sub-genomic RNAs have a VPg covalently bound to its 5' end. The 3' terminus of the genomic RNA is non-polyadenylated. An approximately 100 nt long 5' UTR and up to 289 nt long 3' UTR are supposed to compensate the absence of cap and poly(A) tail. VPg may attach to the genome via phosphodiester bond formed through tyrosine, serine, or threonine residues, depending on the viral species. The 5' UTR of sobemoviruses comprise a polypurine tract and 3' UTR are more diverse. In the case of CfMV, 5' UTR acts as an enhancer of translation and 3' UTR seems to contain sequences or structures important for the transport of viral RNA. For this virus, as well as for RYMV, a potential tRNA-like structure has been predicted at the 3' UTR. SeMV 3' UTR has a stem-loop 28–55 nt upstream of the 3' end that is important for RNA-dependent RNA polymerase (RdRp) template recognition. Interestingly, also the polemovirus Poinsettia latent virus (PnLV) has a stable hairpin at its 3' UTR, which buries the last nucleotide. Not all, but most of the solemoviral genomes – including PnLV – have a conserved 5' sequence ACAA(AA), considered to play a role in viral RNA replication. This motif is also present upstream of the translation initiation codon of CPs, as a possible 5' terminus of sgRNA.

In addition to the approximately 1 kb sgRNA encoding the CP, PnLV has a larger putative sgRNA of 2.60 kb. Further studies are needed to find out whether this is a real sgRNA or a defective RNA. In fact, sobemovirus CfMV particles may contain different defective interfering RNAs (diRNA).

Fig. 2 Genome organization of the genera *Solemovirus* and *Polemovirus* in the family *Solemoviridae*. Comparison of the genome organization of Southern bean mosaic virus (SBMV) and Poinsettia latent virus (PnLV), type species of the corresponding genera. ORFs encoding proteins sharing sequence homology are indicated in similar colors: silencing suppressor (violet), serine protease-VPg-s (red), RNA-dependent RNA polymerases (yellow), coat proteins (green). VPg-s are depicted as red dots at the 5'-end of the genomic RNA. Proteins with unknown function and no sequence homology are shown in gray. Non-canonical AUG start codon is marked with asterisk (*). – 1 ribosomal frameshifting is marked by long vertical dashed line.

A. RNA-dependent RNA polymerases

B. Coat proteins

Fig. 3 Maximum-likelihood trees showing phylogenetic relationships between solemoviruses and viruses belonging to related families. Phylogenetic relationships between members of the genera *Sobemovirus* (family *Solemoviridae*, shown in green), *Polemovirus* (family *Solemoviridae*, shown in teal), *Polemovirus* (family *Luteoviridae*, shown in blue), *Enamovirus* (family *Luteoviridae*, shown in turquoise), *Luteovirus* (family *Luteoviridae*, shown in orange), *Alphaneecrovirus* and *Betanecrovirus* (family *Tombusviridae*, shown in red), *Barnavirus* (family *Barnaviridae*, shown in violet), and *Dinornavirus* (family *Alverniviridae*, shown in gray) demonstrate the discordant placement of these genera on the unrooted maximum-likelihood (ML) trees. ML trees based on amino acid sequence alignments were predicted for RNA-dependent RNA polymerases (RdRps, panel A) and for coat proteins (CPs, panel B). Genera *Polemovirus* and *Luteovirus* are represented by a reduced number of species. Species officially recognized by ICTV are shown in italics. The ML trees were calculated with 1000 bootstrap replicates using the Whelan and Goldman (WAG) model for RdRps and Le Gascuel (LG) model for CPs. The percentage of trees in which the associated taxa clustered together is shown next to the branches if >70. Branch lengths are proportional to genetic divergence. Scale indicates the number of amino acid substitutions per site.

Solemoviruses differ in the 5' terminal part of their genomes. This is part of the differences between the members of the genera *Polemovirus* and *Sobemovirus*. Indeed, the name *Polemovirus* comes from *polemovirus* and *sobemovirus* to indicate the chimeric nature of this genus: the 5'-three quarters of the genome are similar in organization and sequence to polemoviruses (polemoviral RdRp groups together with polemoviral RdRps, Fig. 3(A)) and the CP shares the highest homology with sobemoviruses (Fig. 3(B)).

The most 5' proximal ORF in the case of polemovirus is ORF0 that encodes a protein of 30 kDa of unknown function. Sobemoviruses first ORF is called ORF1 and encodes the protein P1, a suppressor of RNA silencing. P1 is dispensable for replication and is suspected to be the viral movement protein, as it has been shown to be required for systemic infection. Moreover, in the case of SeMV, P1 has been shown to interact with its genome-bound VPg and with P10, an ATPase that could

supply the needed energy for an active transport. It remains to be elucidated, if P1 RNA silencing suppressor function is uncoupled from its role in viral movement. The only conserved element among sobemoviral P1 is a Zn-finger motif that is required for suppressing RNA silencing. ORF1 partially overlaps the small ORF_x from which the P_x protein is translated. The translation initiation codon of ORF1 is located in an unfavorable context and therefore a leaky scanning of ribosomes occurs. Since P_x translation starts from a non-AUG codon, protein synthesis rates are very low. P_x is a protein of unknown function and it has been shown to be needed for viral infection in the case of Turnip rosette virus (TRoV). ORF_x and ORF1 are the most variable regions in sobemoviral genomes. No small ORF has been detected for polemovirus PnLV.

All solemoviruses comprise at the central part of their genome two overlapping ORFs. The second ORF always encodes the RdRp that is translated via -1 ribosomal frameshifting. Polemoviral ORF1 contains putative helicase and protease domains as well as a predicted VPg sequence in-between (altogether the product is 72 kDa), while ORF2 encodes the RdRp (122 kDa). In the case of sobemoviruses, the ineffective initiation of translation of P1 and P_x proteins allows the expression of ORF2a that encodes the most abundant polyprotein P2a. ORF2a encodes an N-terminal trans-membrane anchor (TM), a virus serine protease (Pro) and the VPg. The exact functions of the proteins encoded by the C-terminal portion of ORF2a are unclear, but this part has been shown to have ATPase and NTP-binding properties and is further processed to P10 and P8, at least in the case of SeMV. Sobemoviral ORF2b is expressed as a fusion protein with ORF2a through -1 ribosomal frameshifting shortly after VPg domain. For CfMV it is known that in 10%–20% of the cases the longer version polyprotein P2ab (TM–Pro–VPg–RdRp) is translated instead of the regular polyprotein P2a (TM–Pro–VPg–P10–P8). The -1 ribosomal frameshift is needed to regulate the production of sobemoviral RdRp, which is encoded by ORF2b and involves two elements: a slippery sequence conserved among sobemoviruses (UUUAAAC) and a stem-loop located 7 or 8 nt downstream of it. PnLV slippery sequence for RdRp translation seems to be GGGAAAC, shared by some poleroviruses.

Proteolytic cleavages in the polyproteins are carried out by the viral serine protease that cuts at E/T residues for SBMV, at E/N and E/T residues for CfMV, at E/S and E/T residues for RYMV and at E/S residues in the case of RGMoV. The C-terminal cleavage of VPg takes place upstream of the slippery sequence. SeMV is the only solemovirus for which all four cleavage sites have been characterized and its protease domain has been crystallized. The structure exhibits the characteristic features of trypsin fold. Mutations of glutamate-binding site residues H298, T279, and N308 render the protease inactive. Pro–VPg is crucial for protease activity and this precursor protein accumulates in membranes of infected cells. Notably, Pro–VPg is released from P2a, while Pro is detected when P2ab is expressed. TM putative function is to anchor the polyprotein into cellular membranes to facilitate proteolytic processing and probably minus strand synthesis.

If no VPg processing occurs, the virus is not viable. VPg is an intrinsically disordered protein that is able to bind different partners. SeMV VPg has been shown to interact with P1 but not with RdRp. Importantly, RYMV VPg interacts with eukaryotic translation initiation factor eIF(iso)4G and it seems that also P8 is involved in this binding. SeMV P8 contains an RNA binding region and is needed for the ATPase activity of P10 in the precursor P10–P8. SeMV P10 partners are P1, as mentioned before, and RdRp, meaning that this protein may be related to virus movement and replication.

According to their sequences, RdRp-s of solemoviruses are grouped together with the RdRps of polero-, enamo-, and barnaviruses (Fig. 3(A)). This is the so-called “sobemo-lineage” in the supergroup I of plus-sense plant RNA viruses. RdRps of this group seem to lack the NTP-binding region conserved in viral helicases. The GDD motif (SGSYCTSSSTNX_{19–35}GDD) that characterizes RdRps of RNA viruses with ssRNA and positive polarity genomes is essential. Studies on SeMV RdRp have shown that it can synthesize RNA in a primer-independent manner. This polymerase interacts at its C-terminal region with P10 that apparently catalyzes RdRp activity.

Some solemoviral CPs are related to processes different to capsid formation. CP of SeMV has been reported to interact with P1, protein related to viral movement, as explained before. Interestingly, CP of CfMV has been shown to act as suppressor of RNA silencing, in addition to P1.

Phylogenetic Relationships

The viruses belonging to the families *Solemoviridae*, *Luteoviridae*, and *Tombusviridae* seem to have evolved via recombinational shuffling of the genes encoding the protease, RdRp and CP. The sequences of solemoviral long polyproteins are similar to the polyproteins of polero- and enamoviruses (genera belonging to the family *Luteoviridae*), whereas solemoviral CPs share more similarity to CPs of alpha- and betanecroviruses (belonging to the family *Tombusviridae*).

The only known member of the genus *Polemovirus* is the product of a recombination between a polerovirus and a sobemovirus. As mentioned before and as shown in Fig. 3, RdRp of polemovirus PnLV is closely related to poleroviral RdRps, but its CP sequence is highly similar to sobemoviral CPs. It has been proposed that the recombination happened in the presence of a co-infection by switching templates close to the sgRNA start site during replication. Although PnLV shares similar sequences with poleroviruses and sobemoviruses, it is most closely related to the genus *Sobemovirus* than to any other genus and therefore, polemo- and sobemoviruses are grouped into one family.

The phylogenetic trees based on RdRp and on CP sequences show discordant placement of the analyzed species. This corroborates the supposition of possible recombinational events between ancestral solemo-, luteo-, and tombusviruses (Fig. 3). In addition, representatives of other genera (*Barnavirus* and *Dinornavirus*) seem to be involved in this evolutionary process.

Among sobemoviral CPs, sequences from RGMoV, RoMoV, and ArtVA are slightly more similar to CP sequences of several tombusviruses than to other sobemoviral CPs (Fig. 3(B)). As explained above, also the 3D structures of the CPs of these three sobemoviruses are predicted to be closely related to tombusviral CPs.

Studies comparing related viruses at the level of their RdRp sequences have concluded that sobemo-, barna-, polero-, and luteoviruses divergence time is around 9000 years. If luteoviruses are not considered, then the divergence is reduced to 5000 years, and leaving apart poleroviruses means going down to 4000 years. Based on this kind of calculations, a hypothesis correlating the development of agriculture to the appearance of different viruses has been raised.

Replication and Movement

The replication of solemoviruses is poorly understood. The genomic RNA of incoming virus particles is probably uncoated by the co-translational disassembly mechanism that is followed by RNA replication once the RdRp has been synthesized.

Little is known about the signals needed for viral replication. As mentioned before, solemoviral genomes have a conserved 5' sequence ACAA(AA) that is also characteristic for 5'-termini of polero-, diantho-, and barnaviruses. This motif is also present at the 5'-terminus of sgRNA. Due to the conservation of this region, the complementary sequence in minus-strand has been predicted to function in replication by promoting or enhancing the binding of RdRp to both genomic and sgRNA. The stem-loop structure found at the 3'-end of some solemoviral genomes is important for template recognition by RdRp and thus, for the synthesis of minus-strand. It is not yet clear, whether solemoviral VPg primes the synthesis of viral RNA. SeMV VPg has been shown to be dispensable for *in vitro* synthesis of minus-strand RNA.

At least five diRNA molecules have been cloned from CfMV-infected plants. Their sequences consist of the 5'-terminal 35–40 nt linked to the 850–950 nt of the 3'-terminus. This indicates the possibility that RdRp is able to switch templates and create recombinant RNA molecules.

In addition to the viral genome, RdRps of some solemoviruses also replicate satRNAs. These are 220–390 nt circular molecules that are replicated by a helper virus. satRNAs have several interesting interactions with the replication of the helper viruses. For example, LTSV supports the replication of satRNA of SNMoV but SNMoV does not replicate LTSV satRNA. At the same time, LTSV satRNA replication is supported by CfMV, SBMV, Sowbane mosaic virus (SoMV), and TRoV, whereas this support is host dependent. Importantly, satRNAs influence sometimes the symptoms caused by the helper virus. satRNAs are predicted to have viroid-like secondary structures and replicate via rolling circle mechanism. After replication, monomers are self-cut by endogenous hammerhead ribozyme structures. RYMV satRNA is the smallest described so far (220 nt long). Remarkably, LTSV satRNA encodes a protein of 16 kDa with unknown function. Since the length of the circular genome is not a number divisible by three, translations happen one after another continuing from different codons in each round.

Solemoviral particles are detected mainly in mesophyll and vascular tissues, but also in epidermal, bundle sheath, guard cells, and even in meristem cells, depending on the viral species. Concerning vascular tissues, virus particles have been reported in both xylem and phloem: CfMV, SCPMV, and SBMV particles have been found mainly in the phloem, whereas RYMV, SoMV, and Blueberry shoestring virus (BSSV) virions have been detected predominantly in the xylem. CfMV particles have been reported in phloem parenchyma and bundle sheath cells, when infection starts. In later stages of infection, CfMV spreads in mesophyll cells surrounding vascular bundles and is only seldom present in xylem parenchyma.

At the subcellular level, virus particles are found in cytoplasm, vacuoles, and nuclei. Some sobemoviruses have NLS signals in their CP sequences that make a nuclear localization of the virion feasible. At late stages of infection, particles accumulate forming crystalline structures in the cytoplasm or vacuoles. No particles have been detected in mitochondria and chloroplasts, but the latter are noted to form finger-like extrusions in infected cells.

Studies with solemoviruses emphasize that cell-to-cell and long-distance (systemic) movement are two distinct processes. For the latter movement, correct particle formation may be essential. This is the case for SCPMV and RYMV. Indeed, studies with full-length clones of these two viruses have shown that CP is dispensable for virus replication but systemic virus movement is completely abolished in the absence of CP. In the case of SeMV, it has been proven that its virion and CP itself interact with P1, the protein related to virus movement. On the contrary, experiments with CfMV lacking CP demonstrated that this virus does not need CP for cell-to-cell or for systemic movement, implying that it moves as a ribonucleoprotein complex and not as viral particle. However, CP-deficient CfMV was not able to be transmitted mechanically using sap-inoculation.

An efficient transmission of solemoviruses by vectors is facilitated by a correct virion formation that is resistant to RNases present in the regurgitant or in the hemolymph and even in feces of insects.

Host Range and Transmission

The host range of individual solemoviruses is narrow – limited to one plant family – with the exception of SoMV that naturally infects plants from the families *Chenopodiaceae*, *Vitaceae*, and *Rosaceae*. Genetic relationships are stronger between virus species infecting plants from the same family. Most of the so far sequenced solemoviruses infect dicotyledonous plants. According to phylogenetic data, commelinid (*Poales*)-infecting sobemoviruses have emerged at least twice during diversification of sobemovirus species.

The main route of transmission for solemoviruses is mechanical wounding of plants. In addition, transmission from soil has been suggested for many solemoviruses. The polemovirus PnLV is distributed by grafting and vegetative propagation of the host plant; however, the natural means of transmission remains unknown. Viruses in the genus *Sobemovirus* are transmitted by vectors like beetles, aphids, bugs, and thrips. Interestingly, phylogenetically related sobemoviruses may have vectors that belong to different orders. In the case of RYMV, it has been shown that the virus is transmitted over short distances by herbivore mammals and trampling livestock. Importantly, several sobemoviruses are seed-transmissible.

Pathological and Epidemiological Aspects

The polemovirus PnLV is spread worldwide in cultivated poinsettia (*Euphorbia pulcherrima*) plants without causing symptoms. Equally, some sobemoviruses do not provoke symptoms in their host plants. However, in most cases, solemoviral infections induce symptoms like chlorosis at different levels, mosaic or mottling patterns on leaves. In addition, stunting, necrosis, vein clearing, and even sterility have been reported. The outcomes depend on the specific virus, the host and other factors like environmental conditions and the number of viral particle present in the infected plant.

As said, solemoviruses form crystalline arrays and tubules in the cytoplasm. Some of these structures are enveloped in endoplasmic reticulum-derived vesicles. Viral particles from some solemoviruses are associated with chloroplast membranes and thus, induce changes in the structure of this organelle. In CfMV- and SoMV-infected cells, a proliferation of tonoplast membranes that bulge into the vacuole takes place. Many cytological changes have been observed in RYMV-infected cells. Probably the most dramatic change induced by this virus occurs in the cell walls of parenchyma and mature xylem cells, where middle lamellae of the wall are disorganized.

RYMV infection also causes important changes in the abundance of host proteins. For instance, the expression levels of several defense- and stress-related proteins like superoxide dismutase and different heat shock proteins increase several times. The changes in the levels of antioxidant enzymes and production of reactive oxygen species has been analyzed in cocksfoot plants infected with CfMV. Susceptible plants and plants with acquired resistance showed completely different regulation of the levels of antioxidant enzymes and reactive oxygen species after inoculation with CfMV.

Natural resistance to solemoviruses has been detected at least for CfMV in cocksfoot, for SBMV in beans, for SCMoV in subterranean clover, for SCPMV in cowpea and for RYMV in different *Oryza* species including rice. The molecular mechanisms conferring resistance have only been described for RYMV in *Oryza* species. Pathogen-derived transgenic resistance against RYMV has been achieved by transforming plants with constructs expressing parts of ORF2. However, this RNA silencing-based resistance is low compared to natural resistance that is being exploited to obtain RYMV-resistant rice varieties.

ssRNA single-stranded RNA
vcRNA viral complementary RNA
vRNA virion RNA
VSR Viral suppressor of RNA silencing

Glossary

Ambisense polarity The presence of open reading frames (ORFs) in both the vRNA and its vcRNA, means that both strands encode proteins. This expression strategy requires strong transcription termination signals to avoid the synthesis of complementary RNA and the formation of double stranded RNA that may induce RNA silencing.

Cap-snatching A mechanism of viral mRNA synthesis by the viral RdRp that cleaves off several nucleotides from the 5' terminus of host capped mRNAs and used them as primers to initiate transcription.

Movement protein This refers to a viral protein that in plants assists in cell-to-cell movement of viral complexes through the plasmodesmata before systemic transport through the plant vascular system.

Persistent viral transmission This is a mode of transmission of a plant virus by an insect vector in which the virus after entering the body of the vector, replicates and circulates for systemic invasion of vector insect tissues during days to weeks. The virus passes through the insect's midgut and salivary gland barriers for transmission to new host plants.

RNA silencing An evolutionarily conserved mechanism that is active in many eukaryotic organisms (plants and insects) as antiviral defense. It is a sequence-specific gene-silencing process induced by double-stranded RNA that is either targeted for degradation by the RNA-induced silencing complex or for translational repression.

RNA silencing suppressor A viral factor or protein that counteracts the host plant RNA silencing defense response.

Introduction

The tenuiviruses were first described in the Fifth Report of the International Committee on Taxonomy of Viruses in 1982 as non-enveloped plant viruses possibly possessing a negative ssRNA genome. Their name comes from the Latin 'tenuis', (thin, fine, weak) that refers to the structure of the viral particle as seen by electron microscopy (Fig. 2). Epidemics of Rice stripe virus (RSV) and Rice hoja blanca virus (RHBV), two members of the genus *Tenuivirus*, cause important yield losses in rice-growing areas of Asia and the former USSR, and of tropical South America, respectively. Tenuiviruses exhibit unique properties that make them different from other plant viruses.

Some properties of tenuiviruses are the following:

- (1) The peculiar flexuous viral particles have a thread-like morphology and can adopt circular forms (Fig. 2 Left).
- (2) A non-structural protein (NS4) also designated disease specific (DS) protein (16–22 kDa) accumulates in large amounts in infected plants, forming large inclusions (Fig. 2 Right).
- (3) The viruses are persistently transmitted by a species of planthopper (Fig. 5 Bottom) in a propagative manner. For some of the members of the genus it has been demonstrated that the virus multiplies both in the host plant and in the insect vector. Multiplication of the virus in the vector may have deleterious effects on the insect. The viruses can be transmitted transovarially by viruliferous female planthoppers to their offspring, and through sperm from viruliferous males. The ability to disseminate and to infect reproductive tissues is a prerequisite for the transovarial transmission of tenuiviruses.

- (4) The genome of tenuiviruses is multi-segmented and composed of ssRNAs that have either a negative or an ambisense polarity (Fig. 3).
- (5) An RdRp is associated with the viral particle.
- (6) It has been observed for some tenuiviruses that the mRNAs are synthesized via cap-snatching (Fig. 4).
- (7) The presence of a highly conserved octanucleotide at the 5' (5'-ACACAAAG) and 3' (CUUUGUGU-3') termini of their genomic segments.
- (8) Tenuiviruses infect crop plants of the family *Poaceae*.

Taxonomy

In 2016 the ICTV grouped under the order *Bunyavirales* all the negative stranded RNA viruses previously classified in the family *Bunyaviridae* and the unassigned “bunyavirus-like” viruses such as the tenuiviruses, in order to better reflect their evolutionary relationships. A total of 12 families were created in the order *Bunyavirales* and the family *Phenuiviridae* was created to group the related phleboviruses and tenuiviruses. Among these 12 families, 3 of them comprise viruses infecting plants; *Fimoviridae*, *Tospoviridae*, and *Phenuiviridae*. The *Phenuiviridae* family clusters 15 genera, and only the genus *Tenuivirus* hosts plant viruses (Table 1). *Rice stripe tenuivirus* (RStV) is the type species of the genus *Tenuivirus*. Other species in the genus are *Echinochloa hoja blanca tenuivirus* (EHBV), *Iranian wheat stripe tenuivirus* (IWSV), *Maize stripe tenuivirus* (MStV), *Rice grassy stunt tenuivirus* (RGSV), *Rice hoja blanca tenuivirus* (RHBV), and *Urochloa hoja blanca tenuivirus* (UHBV). Tentative species are European wheat striate mosaic virus (EWStMV), Maize yellow stripe virus (MYSV), and Melon chlorotic spot virus (MChSV) (Table 2).

Classification

The criteria for species demarcation are given as follows:

- (1) Vector specificity: transmission by different vector species.
- (2) Different sizes and/or numbers of RNA segments.
- (3) Host range: ability to infect different key plant species.
- (4) Amino acid (aa) sequence identity of less than 85% between corresponding gene products.
- (5) Nucleotide (nt) sequence identity of less than 60% between corresponding non-coding intergenic regions.

An example of species discrimination is that between RStV and MStV. RStV is transmitted by *L. striatellus* and infects 37 graminaceous species including rice and wheat. MStV is transmitted by *P. maidis* and infects maize, occasionally sorghum, and a few other graminaceous plants but not rice or wheat. Finally, RStV isolates have genomes of four RNA segments and the MStV genome consists of five segments.

An example of difficult species demarcation is the group of the hoja blanca viruses (RHBV, EHBV, and UHBV). They have different vectors, different sizes and numbers of RNA segments, different hosts, and the nt sequence identity of their intergenic regions is less than 60%. However, the aa sequences of the four proteins on RNAs 3 and 4 are about 90% identical between RHBV, EHBV, and UHBV. Since four of five criteria are met, these viruses could be considered as distinct species that possibly separated recently and are now diverging with little field contact between them. Phylogenetic analysis of the sequence data from RNA3 and RNA4 of the tenuiviruses shows that RHBV, EHBV, and UHBV are related and form a group distinct from RStV and MStV (Fig. 1). IWSV was recently included as a member of the tenuivirus genus, it is related but distinct from RHBV and EHBV based on the phylogenetic analysis of RNA 3 and RNA 4 (Fig. 1) as well as on serology.

Virion Structure

Morphology

The particles also referred to as ribonucleoproteins (RNPs) are thin filaments that appear circular (Fig. 2 Left) or spiral shaped. The RNPs are 3–10 nm in diameter, with lengths proportional to the sizes of the RNAs they contain. No envelope has been observed.

Physical and Physicochemical Properties

RNP preparations can be separated into four to six components by sucrose density gradient centrifugation; they correspond to the four to six RNA segments coated in the nucleocapsid protein (NC). The buoyant density of the RNP in CsCl when centrifuged to equilibrium is 1.282–1.288 g cm⁻³. The RNA constitutes 5%–12% of the particle weight.

^aPartial sequence.

Components

The RNPs contain RNA coated with the NC protein of 34–35 kDa, and small amounts of the RdRp of 230–330 kDa. The RdRp associated with the RNPs of RStV and RHBV is capable of replicating and transcribing the RNA segments *in vitro*. The tenuivirus genome is composed of four to six non-capped ssRNA segments. The approximate size of the genome of the type member RStV is 17 kb (**Fig. 3**). The largest RNA segment (9.0 kb) of RStV, MStV, and RHBV is of negative polarity and encodes the RdRp. RNA2 (3.3–3.6 kb), RNA3 (2.2–2.5 kb) and RNA4 (1.9–2.2 kb) of RStV, MStV, IWSV, EHBV, UHBV, and RHBV are ambisense. RNA5 (1.3 kb), detected in virions of MStV and of EHBV is of negative polarity. A fifth RNA segment has also been reported for some

Fig. 1 *Phylogenetic relationships of tenuiviruses.* Phylogenetic tree showing the relationships between tenuiviruses on the basis of the nucleotide sequences of the coding regions of RNAs 3 and 4 for all tenuiviruses except RGSV for which the coding regions of RNAs 5 and 6 were used. Shown is the percentage bootstrap support at each node. Echinochloa hoja blanca virus (EHBV), Iranian wheat stripe virus (IWSV), Maize stripe virus (MSpV), Rice grassy stunt virus (RGSV), Rice hoja blanca virus (RHBV), Rice stripe virus (RStV) and Urochloa hoja blanca virus (UHBV). The following sequences were used: EHBV (L48441, L75930), IWSV (AY312436, AY312435), MSpV-US (L13438, M57426), RGSV-PH (AB000404, AB000403), RGSV-CN (AF287949, AF290947), RHBV-CO (L14952, AF004658), RHBV-CR (AF004657, L07940), RSV-JP (D10979, X53563), RSV-CN (Y11096, Y11095) and UHBV (U82446, U82447). The MUSCLE multiple alignments and the phylogenetic tree were performed using Phylogeny. fr (<http://www.phylogeny.fr/index.cgi>), as described in Dereeper, A., Guignon, V., Blanc, G., *et al.*, 2008. Phylogeny. fr: Robust phylogenetic analysis for the non-specialist. Nucleic Acids Research. 36 (Web Server issue), W465–W469.

isolates of RStV. RGSV RNA1, 2, 5, and 6 are homologous to RNA1, 2, 3, and 4, respectively, of other tenuiviruses. RGSV RNA3 (3.1 kb) and RNA4 (2.9 kb) are ambisense and unique to RGSV.

Genome Organization

The 5' and 3' terminal sequences (about 20 nt) are complementary to each other and can base-pair to give rise to circular RNPs. The terminal 8 nt (5' ACACAAAG) and their complement are conserved between tenuiviruses and viruses of the genus *Phlebovirus*. Several RNA segments encode two proteins in an ambisense arrangement (Fig. 3).

The RStV gene products of each RNA segment are: - The RdRp (337 kDa) is encoded by the viral complementary vcRNA1, - The p2 (23 kDa) is present in the RNA2 and the pC2 (94 kDa) in the vcRNA2, - The p3 (24 kDa), also designated NS3, is encoded by the vRNA3. NS3 is a viral suppressor of RNA silencing (VSR) as demonstrated for RStV and for RHBV in both plant and insect hosts. The NC protein (35 kDa), also designated N or pC3, is encoded by the vcRNA3. The major non-structural protein NS4 (21 kDa), also designated p4 or disease-specific protein, is encoded by vRNA4. NS4 accumulates in infected plant tissues in large inclusion bodies. RStV NS4 facilitates tissue tropism in the insect vector. Finally, the pC4 (32 kDa), also designated movement protein (MP) or NSvc4, is encoded by the vcRNA4. The MP is implicated in the passage of viruses from cell-to-cell.

Replication and Transcription

The RdRp synthesizes full-length vRNA and vcRNA that are not capped and sgRNAs of different sizes and of either polarity that serve as mRNA for the synthesis of the corresponding viral proteins. For MStV, RHBV, and RStV, it has been shown that

Fig. 3 Schematic representation of the genome organization of *RStV*. v, viral sense RNA. vc, viral complementary RNA. RdRp, RNA-dependent RNA polymerase. NS3, non-structural protein 3 that acts as viral suppressor of RNA silencing (VSR). NC, nucleocapsid protein. NS4, non-structural protein that accumulates in viral inclusion bodies in infected plant tissues; it is also designated disease-specific (DS) or non-capsid protein (NCP). MP, movement protein.

Fig. 4 Schematic representation of the replication, transcription, and translation strategies of the ambisense RNA segments of tenuiviruses. The cap and the non-viral nucleotides of host origin used as primers by the RdRp as a result of cap-snatching are represented at the 5' end of the mRNA. IR, intergenic region.

these mRNAs are synthesized via cap-snatching (**Fig. 4**). The 5' end of the mRNAs contains 10–17 non-viral nt and are capped; these extra sequences are derived from host cell mRNAs that are taken or snatched by the RdRp and are used as primers to initiate mRNA synthesis. Intergenic non-coding regions located between the ORFs can in certain cases adopt hairpin structures. The cap-snatching mechanism has been observed for mRNA synthesis of influenza viruses and viruses of the order *Bunyavirales*.

Biological Properties

Host Range and Geographic Distribution

Plant hosts of tenuiviruses all belong to the family *Poaceae*. Members of the genus *Tenuivirus* cause severe disease in important food cereal crops such as rice and maize and their planthopper vectors themselves are also serious crops pests. Tenuiviruses-induced diseases are economically important resulting in serious yield losses. RStV was estimated in the 1960s to affect around 19% of the total Japan's rice area. RHBV was reported to be responsible of 25%–75% yield losses in Latin American rice, and MSpV-associated losses in maize of 80% were reported from Mauritius.

The geographic distribution of tenuiviruses is determined by the presence of their vector. RStV and RGSV are limited to the Far East, especially in China, Japan, and Korea; RHBV and EHBV to tropical and subtropical regions of the Western Hemisphere, Central and South America, the Caribbean, and the Southern United States; and MSpV has the most widespread geographic distribution around the world but only in subtropical and tropical regions.

Cytopathology

In infected plants large inclusion bodies (Fig. 2 Right) are observed that contain the major non-structural protein NS4.

Disease Symptoms and Control

Typical disease symptoms induced by tenuivirus on host plants are chlorotic stripes and yellow stipplings on the leaf blade between the veins, as well as plant dwarfing and panicle sterility. Young infected plants often exhibit complete chlorosis on the emerging whorl leaf and symptom severity and subsequent yield losses vary with age of the plant at the time of infection. RStV-infected rice leaves show yellow strips and dead tissue streaks. RHBV (Fig. 5 Top) and EHBV induce chlorotic leaf striping and mottling - called white leaf or *hoja blanca* -, plant dwarfing, panicle sterility, premature wilting, and necrosis, causing serious yield losses. MSpV-infected maize plants show early leaf chlorosis between the veins that later develop into continuous stripes, often with a “brush-out” appearance toward the tip of stripes.

RStV-induced disease has been successfully controlled in Japan and China during the last few decades by using naturally resistant rice. RGSV causes significant economic losses in rice production in South, Southeast, and East Asian countries and

Fig. 5 Disease symptoms and insect vector. (Top Left) RHBV-infected chlorotic rice leaf with *hoja blanca* striping and mottling. (Top Right) RHBV-infected rice panicle. Healthy leaves and panicle are shown for comparison. (Bottom) *Tagosodes orizicolus* vector of RHBV.

suitable resistance genes against RGSV have not yet been found in natural rice resources. A promising method to confer resistance against tenuiviruses is the use of RNA interference to target viral genes NC and MP that play important roles in viral infection and proliferation at an early stage of viral replication. Transgenic plants have been reported to show resistance against RStV and RGSV infection and inhibited the proliferation of the virus.

In the 1980s, the identification of RHBV as the causal agent of the hoja blanca disease of rice together with genetic studies on the interaction of this virus with its planthopper vector, confirmed the pathogenic nature of the virus to its vector and helped to explain the cyclical nature of the epidemics. This disease was first controlled by hybridization of susceptible indica and resistant japonica rice genotypes and the adoption of integrated disease control practices. Recently, new RHBV-resistance sources belonging to the indica type have been identified; making it feasible to use these potential sources in crosses targeting the tropics.

Insect Vector and Type of Transmission

Each virus species is persistently transmitted by a particular species of planthopper in a propagative manner and can be transmitted transovarially by viruliferous female planthoppers to their offspring, and through sperm from viruliferous males. The principal vectors of the species are *Laodelphax striatellus* for RStV, *Tagosodes cubanus* for EHBV, *Peregrinus maidis* for MStV, *Nilaparvata lugens* for RGSV, *Tagosodes orizicolus* for RHBV (Fig. 5 Bottom), *Ukanoes tanasijevici* for IWSV and *Caenodelphax teapae* for UHBV. Known vector of the tentative species is *Javesella pellucida* for EWStMV.

Relation to Other Taxa

Viruses of the genus *Tenuivirus* share several properties with those of the genus *Phlebovirus*. The multi-segmented genomes of tenuiviruses and phleboviruses contain negative-sense and ambisense components. The presence of the highly conserved octanucleotide at 5' (5'-ACACAAAG) and 3' (CUUUGUGU-3') termini of their genomic segments, these terminal complementary sequences can base-pair and may give rise to circular RNPs. The synthesis of mRNAs by the viral RdRp follows a cap-snatching mechanism for viruses of the two genera. In addition, they encode functionally related proteins at equivalent genome positions: the tenuivirus RdRp and 94 kDa proteins are homologous to the RdRp and glycoproteins of other members of the family *Phenuiviridae*. Finally, their infection cycle includes arthropod transmission and the ability to replicate in the arthropod vector.

The different number of genome components and the apparent lack of an enveloped viral particle distinguish tenuiviruses from other viruses of the family *Phenuiviridae*. Tenuiviruses are more complex in terms of the number of genome segments and generally encode more proteins than phleboviruses. However, differences in number of genome segments are not uncommon traits among genera of viruses belonging to the same family (e.g., *Reoviridae*, *Closteroviridae*, *Secoviridae*, *Potyviridae*, *Rhabdoviridae*), or even between members of the same genus (e.g., *Emaravirus*). Although enveloped tenuivirions have not been found, tenuiviruses do encode a glycoprotein closely related to those of phleboviruses (a similar situation can be found in the family *Rhabdoviridae* among members of the genus *Dichorhavirus*).

Glossary

Co-translational disassembly A biological phenomenon by which translation of the tobacco mosaic virus (TMV) occurs simultaneously as the disassembly of the TMV particle.

Cryptotope A determinant (or epitope) of an immunological antigen or immunogen which is initially hidden and becomes functional only when the molecule is broken or degraded.

Heterospecific antibodies Antibodies that are unable to react with the immunogen used to produce them but are capable to recognize immunogens from other species or mutants.

Mapping of epitopes Epitope mapping is the process of experimentally identifying the binding sites, or "epitopes", of antibodies on their target antigens.

Movement protein A movement protein is a non-structural protein which is encoded by some plant viruses to enable their movement from one infected cell to neighboring cells.

Neotope Types of epitopes which depend on the protein quaternary structure and are absent in dissociated protein subunits.

Segmental mobility in proteins The mobility of an antigenic determinant may make it easier to adjust to a pre-existing antibody site not fashioned to fit the exact geometry of a protein.

Serological differentiation index Serological cross-reactivity between two viruses expressed as the number of two-fold dilutions steps separating homologous and heterologous titers.

Viral mutants The term mutant is also applied to a virus with an alteration in its nucleotide sequence.

Virus disassembly The disassembly of TMV particles is initiated when the end of the particles containing the 5' terminus of the RNA becomes associated with ribosomes.

Virus self-assembly Biological phenomenon by which the different components of a virus particles are capable, under certain conditions, to auto-assemble to form complete and functional virus particles.

The Beginnings of Virology

Tobacco mosaic virus occupies a unique place in the history of virology and was in the forefront of virus research since the end of the nineteenth century. It was the German Adolf Mayer, working in the Netherlands, who in 1882 first described a severe disease of tobacco which he called tobacco mosaic disease. He showed that the disease was infectious and could be transmitted to healthy tobacco plants by inoculation with capillary glass tubes containing sap from diseased plants. Although Mayer was not able to isolate a germ as the cause of the disease, he did not question the then prevailing view that all infectious diseases were caused by microbes and he remained convinced that he was dealing with a bacterial disease.

About the same time, in St. Petersburg, Dmitri Ivanovsky was studying the same disease and he reported in 1892 that when sap from a diseased tobacco plant was passed through a bacteria-retaining Chamberland filter, the filtrate remained infectious and could be used to infect healthy tobacco plants. Ivanovsky was the first person to show that the agent causing the tobacco mosaic disease passed through a sterilizing filter and this gave rise to the subsequent characterization of viruses as filterable agents. A virology conference was held in 1992 in St. Petersburg to celebrate the centenary of this discovery. Although Ivanovsky is often considered one of the fathers of virology, the significance of his work for the development of virology remains somewhat controversial because all his publications show that he did not really grasp the significance of his filtration experiments. He remained convinced that he was dealing with either a small bacterium or with bacterial spores and never appreciated that he had discovered a new type of infectious agent.

Following in the footsteps of Mayer, Beijerinck in Delft, Holland, showed in 1898 that sap from tobacco plants infected with the mosaic disease was still infectious after filtration through porcelain filters. He also demonstrated that the causative agent was able to diffuse through several millimeters of an agar gel and he concluded that the infection was not caused by a microbe.

Beijerinck called the agent causing the tobacco mosaic disease a *contagium vivum fluidum* (a contagious living liquid), in opposition to a *contagium vivum fixum*. In those days the term *contagium* was used to refer to any contagious, disease-causing agent, while the term *fixum* meant that the agent was a solid particle or a cellular microbe. On the basis of his filtration and agar diffusion experiments, Beijerinck was convinced that the agent causing tobacco mosaic was neither a microbe nor a small particle or corpuscle (meaning a small body or particle from the Latin *corpus* for body). He proposed instead that the disease-causing agent, which he called a virus, was a living liquid containing a dissolved, non-particular and non-corpuscular entity.

Lute Bos has claimed that Beijerinck's introduction in 1898 of the unorthodox and rather odd concept of a *contagium vivum fluidum* marked the historic moment when virology was conceived conceptually. However, it is clear that his definition of a virus as a soluble, living agent not consisting of particles certainly does not correspond to our modern view of what a virus is. It is Beijerinck's insistence that a virus is not a microbe and his willingness to challenge the then widely held view that all infectious diseases are caused by germs that make many people regard his contribution to the development of virology as more important than that of Ivanovsky. In 1998, a meeting held in the Netherlands commemorated the centenary of the work of Beijerinck on TMV. About the same time a meeting was held in Germany to honor the contribution of Loeffler and Frosch who, also in 1898, had shown that the agent causing the foot-and-mouth disease of cattle was able to pass through a Chamberland-type filter, in the

same way as TMV. In addition the German workers also established that their disease-causing agent was not able to go through a finer grain Kitasato filter, from which they concluded that the agent, which was multiplying within the host, was corpuscular and not soluble as claimed by Beijerinck. Loeffler, however, continued to believe that his pathogen was a very small germ or spore, invisible in the light microscope, that was unable to cross the small pores of a Kitasato filter.

There is no doubt that none of these 'fathers' of virology realized the nature of the filterable pathogenic agents they were investigating and that the term virus which they used did not have the meaning it has today. It took another 30 years before chemical analysis eventually revealed what viruses are actually made of protein and RNA.

Physical and Chemical Properties of TMV

A major change in our perception of what viruses are occurred in 1935 when Stanley, working at the Rockefeller Institute in Princeton, obtained needle-like crystals of TMV that were infectious and consisted of protein. He used methods that were being developed at the time for purifying enzymes and was greatly helped by a bioassay developed by Holmes in 1929 that made it possible to quantify the amount of TMV present in plant sap. In this assay, extracts containing the virus are rubbed on the leaves of *Nicotiana glutinosa* tobacco plants which leads to a number of necrotic lesions proportional to the amount of virus present.

Stanley's demonstration that TMV was a crystallizable chemical substance rather than a microorganism, a discovery that earned him the Nobel Prize in 1946 and had a profound impact on the thinking of biologists because it suggested that viruses were actually living molecules able to reproduce themselves. For a while, it seemed that viruses closed the gap between chemistry and biology and might even hold the key to the origin of life.

Stanley had originally described TMV as a pure protein, but in 1936 Bawden and Pirie showed that the virus contained phosphorus and carbohydrate and actually consisted of 95% protein and 5% RNA. TMV thus became the first virus to be purified and shown to be a complex of protein and nucleic acid. Following the development of ultracentrifuges in the 1940s, ultracentrifugation became the standard method for purifying TMV and many other viruses.

In 1939, TMV became the first virus to be visualized in the electron microscope and in 1941, TMV particles were shown to be rods about 280 nm long and 15 nm wide. Subsequently, X-ray analysis established that the rods were hollow tubes consisting of a helical array of 2130 identical protein subunits with $16\frac{1}{3}$ subunits per turn and containing one molecule of RNA deeply embedded in the protein subunits at a radius of 4 nm (Fig. 1). The length of the TMV particle is controlled by the length of the RNA molecule which becomes fully coated with protein and is thereby protected from nuclease attack.

The viral protein subunits can also aggregate on their own, without incorporating RNA, to form rods very similar to TMV particles but in this case the rods are of variable length (Fig. 2). It is possible to degrade the virus particles with acetic acid or weak alkali and to obtain in this way dissociated protein subunits and viral RNA, the latter being rapidly degraded by nucleases. In 1956 Gierer and Schramm in Tübingen, Germany, and Fraenkel-Conrat in Berkeley, California, showed that if the viral RNA was obtained by degrading the particles with phenol or detergent, intact RNA molecules were obtained that were infectious and could

Fig. 1 (a) Electron micrograph of negatively stained TMV particles. (b) Diagram of a TMV particle showing about one-sixth of the length of a complete particle. The protein subunits form a helical array with $16\frac{1}{3}$ units per turn and the RNA is packed at a radius of about 4 nm from the helix axis. From Klug, A., 1999. The tobacco mosaic virus particle: Structure and assembly. *Philosophical Transactions of the Royal Society: Biological Sciences* 354, 531–535.

Fig. 2 Diagram showing the different polymorphic aggregates of TMV coat protein obtained at different pH values and ionic strengths. Note that both polar and nonpolar stacked disks can be obtained. The “lock-washer” is not well defined and represents a metastable transitory state. Adapted from Durham, A.C.H., Klug, A., 1972. Structures and roles of the polymorphic forms of tobacco mosaic virus protein. *Journal of Molecular Biology* 67, 315–332, with permission from Elsevier.

produce the same disease as intact virus. This was the first demonstration that the nucleic acid component of a virus was the carrier of viral infectivity and that it possessed the genetic information that coded for the viral coat protein.

In 1960 the TMV coat protein was the first viral protein to have its primary structure elucidated when its sequence was determined simultaneously in Tübingen and in Berkeley and found to consist of 158 amino acids. Subsequently, the coat protein sequence of numerous TMV mutants obtained by treating the virus with the mutagenic agent nitrous acid was also determined and these sequence data helped to establish the validity of the genetic code that was being elucidated in the early 1960s in Nirenberg's and Ochoa's laboratories. One of the changes induced by the action of nitrous acid on viral RNA is the nucleotide conversion of cytosine (C) to uracil (U). This changes the codon CCC for the amino acid proline to the codons UCC or CUC for serine and leucine, respectively. In addition, these two codons can be further converted to UUU which codes for phenylalanine. When the coat protein sequences of various TMV mutants were determined, it was found that most of the exchanged amino acids could be attributed to C→U nucleotide conversions, which confirmed the validity and universality of the proposed genetic code.

A particularly interesting mutation present in mutant Ni 1927 was the exchange proline to leucine at position 156 in the sequence which was found to greatly decrease the chemical stability of the virus. It had been known for many years that the virus was resistant to degradation by the enzyme carboxypeptidase and that this enzyme released only about 2000 threonine residues from each virus particle. The C-terminal residue in the coat protein is in fact threonine and the enzyme degradation data were interpreted at the time to mean that the virus particle contained 2000 subunits. However, when the proline at position 156 was replaced by leucine in the mutated protein, the enzyme was able to degrade the protein far beyond the C-terminal residue. The location of a proline near the C-terminus together with the presence of an acetyl group on the N-terminus are actually responsible for the remarkable resistance of the virus to exopeptidase degradation. The same exchange at position 156 in mutant Ni 1927 also led to an interesting discovery in immunology (see below).

Self-Assembly of TMV Particles

Dissociated coat protein molecules of TMV are able to assemble into different types of aggregates depending on the pH and ionic strength (Fig. 2). The disk aggregate is a two-layer cylindrical structure with a sedimentation coefficient of 20S, where each layer consists of a ring of 17 subunits compared with the 16(1/3) molecules present in each turn of the assembled helix. The disks are able to form stacks which can be either polar or nonpolar, depending on the relative orientation of adjacent disks (Fig. 2). Short stacks of disks were shown to be nonpolar by immunoelectron microscopy, using monoclonal antibodies that reacted with only one end of the viral helix but were able to bind to both ends of the stacked disks. Whereas short polar stacks of disks can be transformed via lock-washer intermediates into helices (Fig. 2), this is not possible for nonpolar stacks which cannot be incorporated as such during the elongation process that leads to the formation of RNA-containing virus particles.

It is generally accepted that initiation of TMV assembly from its RNA and protein components requires a 20S protein aggregate, which could be either a disk or a short, lock-washer type proto-helix. The surface of this aggregate constitutes a template which is recognized by a specific viral RNA sequence. The nucleation of the assembly reaction was found to occur by a rather complex process involving a hairpin structure on the viral RNA, known as the origin of assembly sequence (OAS) located about 1000 nt from the 3' end, which is inserted through the central hole of the 20 S aggregate. The nucleotide sequence of the stem-loop OAS hairpin is responsible for the preferential incorporation of viral RNA rather than foreign RNA. Elongation occurs by addition of more protein subunits which pull up more RNA through the central hole. This process requires that the 5' tail of the RNA loops back down the central hole and is slowly "swallowed up" while the 3' tail continues to protrude freely from the other end. This unexpected mechanism was visualized by electron micrographs obtained in Hirth's laboratory in Strasbourg which revealed how particles were growing with both 3' and 5' RNA tails protruding initially from the same end of the particle. The elongation is thus bidirectional and occurs faster along the longer 5' tail by incorporation of 20S aggregates and more slowly toward the 3' end through incorporation of 4S protein. The elucidation of the assembly process was greatly facilitated by the sequencing of the viral RNA which was completed in 1982. TMV RNA consists of 6395 nt and was the first genome of a plant virus to be sequenced completely.

Virus Disassembly

Since TMV particles are extremely stable *in vitro*, it was not at all obvious how the RNA managed to be released from the particles in order to start the virus replication cycle. Using a cell-free translation system, Wilson discovered that the disassembly of TMV particles is initiated when the end of the particles containing the 5' terminus of the RNA becomes associated with ribosomes. This leads to viral subunits becoming dislodged from the particles while the 5' terminal open reading frame in the RNA is being translated by the ribosomes, a process known as co-translational disassembly. This mechanism allows the coat protein subunits to protect the RNA from enzymatic degradation until the particle has reached a site in the infected cell where translation can be initiated.

Antigenicity of TMV

The antigenic properties of TMV have been studied extensively for more than 60 years and these studies have given us much information on how antibodies recognize proteins and viruses. TMV is an excellent immunogen and antibodies to the virus are readily obtained by immunization of experimental animals. When the sequence of TMV coat protein became available, it was possible for the first time to locate the antigenic sites or epitopes of a viral protein at the molecular level. Initial studies focused on two antigenic regions of the coat protein, the C-terminal region (residues 153–158) situated at the surface of virus particles and the disordered loop region (residues 103–112) located in the central hole of the particles which is accessible to antibodies only in dissociated protein subunits (Fig. 3). The C-terminal hexapeptide coupled to bovine serum albumin was used to raise antibodies and the resulting antiserum was found to precipitate the virus and neutralize its infectivity. Since both natural peptide fragments and synthetic peptides were used in this work, Anderer and his colleagues should be credited with the discovery that synthetic peptides can elicit antibodies that neutralize the infectivity of a virus. Only when similar results were obtained with animal viruses 15 years later, did the potential of peptides for developing synthetic vaccines become clear.

Fig. 3 Backbone of the TMV coat protein subunit based on crystallographic data. Residues 94–106 have been omitted because this region, located on the inside of the particle, is disordered. The N and C termini of the protein are located on the outer surface of TMV particles. The position of 7 continuous epitopes (residues 1–10, 34–39, 55–61, 62–68, 80–90, 108–112, and 153–158) is indicated by solid lines. Reproduced from Al Moudallal, Z., Briand, J.P., Van Regenmortel, M.H.V., 1985. A major part of the polypeptide chain of tobacco mosaic virus is antigenic. *EMBO Journal* 4, 1231–1235, with permission from Nature Publishing Group.

It has been known since the 1950s that intact TMV particles and dissociated coat protein subunits harbor different types of epitopes recognized by specific antibodies. Certain epitopes present only on virions are constituted by residues from neighboring subunits that are recognized as a single entity by certain antibodies; other epitopes arise from conformational changes in the protein that result from inter-subunit bonds. Both these types of epitopes which depend on the protein quaternary structure and are absent in dissociated protein subunits have been called neotopes. Another type of epitope known as cryptotope occurs on the portion of the protein surface that is buried in the polymerized rod and becomes accessible to antibodies only in the dissociated subunits.

The mapping of neotopes and cryptotopes on the surface of TMV coat protein was greatly simplified once monoclonal antibodies (Mabs) became available. Many continuous epitopes were identified at the surface of dissociated coat protein subunits by measuring the ability of peptides to react with Mabs or with antisera (Fig. 3). These epitopes were found to correspond to regions of the protein shown by X-ray crystallography to possess a high segmental mobility. This correlation between antigenicity and mobility along the peptide chain was also found to exist in other proteins and was used to develop algorithms for predicting the location of certain epitopes in proteins from their primary structure.

The surface of the protein subunits accessible at either end of the virus particle is different and the one located near the 5' terminus end of the RNA harbors the two helices corresponding to residues 73–89 and 115–135 (Fig. 3). Many Mabs specific for this surface have been obtained and in addition to reacting with both ends of nonpolar stacked disks, they were found to block TMV disassembly by sterically preventing the interaction between RNA and ribosomes. It has been suggested that if such antibodies could be expressed in plants, they might be able to control viral infection by preventing the disassembly of virions.

Another interesting immunological phenomenon was discovered when TMV antibodies were analyzed for their ability to react with certain TMV mutants. It was found that all rabbits immunized with TMV induced the formation of heterospecific antibodies, that is, antibodies that were unable to react with the TMV immunogen but recognized the mutant Ni 1927 quite well. When all the antibodies in a TMV antiserum capable of reacting with TMV were removed by cross-absorption with the virus, it was found that the depleted antiserum still reacted strongly with this mutant which had a single proline → leucine exchange. Apparently the removal of this proline at position 156 exposes binding sites for both peptidases and antibodies that are normally out of reach in the wild-type protein structure. The induction of heterospecific antibodies by immunization with TMV is another illustration of the difference between the antigenicity and immunogenicity of proteins. TMV particles possess the immunogenic capacity of eliciting heterospecific antibodies that react with the Ni 1927 mutant although they do not have the antigenic capacity of reacting with these antibodies. The reverse situation where an antigenic peptide or protein is able to react with a particular antibody but is unable to induce the same type of antibody when used as immunogen is a more commonly observed phenomenon which greatly hampers the development of synthetic peptide vaccines.

Taxonomy and Classification

Many of the viruses that are currently classified in the genus *Tobamovirus* were initially considered to be strains of TMV on the basis of similar particle morphology and ability to cross-react with TMV antibodies. Antigenic relationships between different tobamoviruses have been quantified using a parameter known as the serological differentiation index (SDI) which is the average number of twofold dilution steps separating homologous from heterologous antiserum titers. A close correlation exists between the antigenic distance of two viruses expressed as SDI values and the degree of sequence difference in their coat proteins. It is often accepted that when two viruses differ antigenically by an SDI value larger than 4, they are considered to belong to separate species. This is valid only if relatedness is measured with polyclonal antisera containing antibodies to a range of different epitopes since comparisons made with Mabs specific for a single epitope will emphasize antigenic similarities or differences depending on which region of the protein is recognized by the particular Mab that is used.

Relationships between individual tobamoviruses are nowadays usually assessed by comparisons between viral genomes. Phylogenetic studies have shown that tobamoviruses are very ancient and co-evolved with their angiosperm hosts, which means that they are at least 120 million years old. The *Tobamovirus* genus is one of seven recognized genera in the family *Virgaviridae* and it comprises 37 species.

Replication and Cell-to-Cell Movement of TMV

TMV-infected tissues contain four viral proteins: the 126 kDa and 183 kDa proteins of the replicase complex, the 30 kDa movement protein, and the 17.6 kDa coat protein. TMV replication is initiated by the translation of the viral RNA to produce the replicase proteins and this leads to the synthesis of minus-sense and plus-sense copies of the RNA. Translation of the viral coat protein gene then occurs leading to the assembly of progeny virus particles from full-length genomic RNA and coat protein. The translation of the coat protein and movement protein is controlled by the production of two separate subgenomic mRNAs, a mechanism later found to occur in many other viruses but first demonstrated with TMV.

The mechanism that allows plant viruses to move from cell to cell in their hosts has remained a mystery for many years. The rigid cellulose-rich walls of plant cells impede intercellular communication which occurs only through tubular connections known as plasmodesmata. However, plasmodesmata are too narrow to allow the passage of virus particles. Studies with the 30 kDa TMV movement protein showed that this protein changed the size exclusion limit of the plasmodesmata, allowing the virus to move through them in the form of a thin, less than 2 nm wide, ribonucleoprotein complex consisting of the genomic RNA and the movement protein. Movement proteins that possess RNA-binding properties have subsequently been found in many other plant viruses. Studies with TMV also revealed how plant viruses encode a suppressor to combat the post-transcriptional gene silencing reaction that plants use to fight virus infection.

Biotechnology Applications of TMV

TMV-resistant plants have been obtained by transforming them with a DNA copy of the TMV coat protein gene. This coat protein-mediated resistance is due to the ability of transgenically expressed coat protein to interfere in transgenic cells with the disassembly of TMV particles. Coat protein-mediated resistance has subsequently been obtained with many positive-sense RNA plant viruses.

A portion of the TMV RNA leader sequence, called omega, was shown to enhance the translation of foreign genes introduced into transgenic plants. This translational enhancer has been incorporated successfully in many gene vectors for a variety of applications.

In another type of application, TMV particles have been used as surface carriers of foreign peptide epitopes for constructing recombinant vaccines and producing them in plants. It was found that the N- and C-termini of the TMV coat protein as well as the surface loop area corresponding to residues 59–65 were able to accept foreign peptide fusions without impairing the ability of the resulting chimeric virus to infect plants systemically. Several experimental vaccines against viral and parasitic infections that are based on genetically engineered TMV particles produced in tobacco are currently under evaluation. In conclusion, a series of contingent discoveries made at the beginning of the 20th century focused on TMV as a new type of pathogen which was extremely stable and obtainable in large quantities from infected plants, and this allowed this virus to play a major role in the development of virology. Furthermore, studies of TMV also contributed significantly to the advancement of molecular biology and to our understanding of the physicochemical and antigenic properties of macromolecules.

Bionanotechnology Applications of TMV

Our considerable knowledge of the three-dimensional structure of TMV particles combined with our understanding of the mechanism of virion self-assembly gave rise to numerous applications in the new field of bionanotechnology. This has led, for instance, to the development of efficient vectors for virus-induced gene silencing in plants, the use of virus-derived sequences for the creation of virus-resistant lines of plants and to the fusion of peptides and various metals on the exterior surface of the virus

for creating a variety of TMV -derived nanostructures. It is also possible to encapsidate any RNA molecule provided it contains the OAS of TMV which then leads to the protection of labile RNA against degradation.

TMV -like particles can also be coupled to various organic molecules, including chromophores or polymers, in order to create classes of effective colloids that have potential biomedical applications inside living organisms. TMV-based nanorods of various sizes have been fabricated *in vitro* and some of them have been administered via the bloodstream for developing tumor-targeting agents. It is quite remarkable that a simple viral structure consisting of a single type of protein subunit together with a single molecule of RNA has led to such an enormous number of possible biotechnological applications.

There is of course always another side to a coin, which in this case is the finding that the stability of TMV particles allows the virus to retain its infectivity for several years during the manufacturing process of cigarettes and cigars. TMV RNA has been shown to be present in the saliva of cigarette smokers (but not of non-smokers) and these smokers were also found to have a higher level of anti-TMV IgG antibodies in their blood than non-smokers. TMV antibodies were also found to cross react with the human mitochondrial protein TOMM40L which shares a six residue sequence (FGTGGA) with residues 36–41 of the TMV coat protein which is also a continuous epitope of the viral protein. It cannot be excluded that these antibodies resulting from an antigenic mimicry phenomenon between TOMM40L and TMV may play role in mitochondrial dysfunction implicated in the pathogenesis of Parkinson disease, Alzheimer disease and other degenerative disorders (Liu *et al.*, 2013).

Pseudoknot RNA structure with base pairing between a loop and other regions of the RNA.

History of Tobamovirus Research

Research in the late 1800s on the causal agent of the mosaic disease of tobacco led to the discovery of viruses as new infectious agents. Thus *Tobacco mosaic virus* (TMV), the type species of the genus *Tobamovirus*, became the first virus to be discovered, and subsequently has had a significant role in many fundamental discoveries in virology. The first quantitative biological assay for plant viruses was the use of *Nicotiana glutinosa* plants, which produce necrotic local lesions when inoculated with TMV or other tobamoviruses. The resistance gene, N, that confers this hypersensitive response-type resistance to TMV was the first resistance gene against a plant virus to be cloned and characterized. TMV was also the first virus to be purified and crystallized, which led to the discovery of the nucleoprotein nature of viruses and determination of the atomic structure of the coat protein (CP) and the virion. TMV was the first virus to be visualized in the electron microscope, confirming the predicted rigid rod-shaped virions. The genetic material of TMV was shown to be RNA, a property previously thought to be restricted to DNA. The first viral protein for which an aa sequence was determined was the TMV CP. TMV was also the first virus to be mutagenized. The subsequent determination of the CP sequences from a number of strains and mutants helped establish the universality of the genetic code. Methods of infecting plant protoplasts with viruses were developed with the tobacco-TMV system, creating a synchronous system to study events in the infection cycle. The TMV 30 kDa protein was the first viral protein shown to be required for virus movement. Finally, TMV was the first plant virus genome to be completely sequenced in 1975.

Taxonomy and Classification

The genus *Tobamovirus* has been assigned to the family *Virgaviridae*. Currently, there are 38 recognized species within the genus (Table 1). Several recently sequenced viruses are tentative members of new species in the genus (Table 1). Although tobamoviruses comprise one of the more intensively studied plant virus genera, taxonomy has often been confusing. Historically, plant viruses with rigid virions of approximately 18 × 300 nm and causing various diseases were all designated strains of TMV. Thus, many viruses originally referred to

as TMV are now recognized as belonging to separate species. For example, the tobamovirus that was referred to as the tomato strain of TMV, and is approximately 80% identical to TMV at the nt sequence level, is now recognized as a different species, *Tomato mosaic virus* (ToMV). One major criterion for distinguishing the members of separate tobamovirus species is a nt sequence difference of at least 10%.

Evolution

Both nt and aa sequences have been used to suggest evolutionary relationships of these viruses. Phylogenetic trees of the MP, CP, and RdRp replicase ORFs have similar topologies, indicating that this block has remained more or less constant as the viruses evolved. Additionally, the trees appear to identify clusters of viruses based on the family of the hosts from which they were identified. Comparison of phylogenetic trees for different coding regions of the genome suggest the clustering of tobamoviruses based on the host family. For example, viruses from solanaceous plants separate from those of cruciferous plant species in all coding regions. Similar congruence of phylogenetic positions is also seen for viruses whose principal hosts are in the *Cucurbitaceae* family. The observations suggest that the viruses were present in plant ancestors to both plant families. The observation that an orchid virus, ORSV, clustered with viruses of solanaceous plants in all but the methyl-transferase region of the replicase, where it branches with viruses from cruciferous plants, challenges that view. Such placement is suggestive that RNA–RNA recombination played a role in evolution of some tobamoviruses (Fig. 1).

Fig. 1 Phylogenetic trees of tobamoviruses based on RdRp (left) and CP (right) gene sequences. The analyses were conducted in MEGA7 using the Maximum Likelihood method based on the Tamura-Nei model and 1000 bootstrap replicates. The tree with the highest log likelihood is shown. The percentage of trees in which the associated taxa clustered together is shown next to the branches (where > 60%). The scale indicates the number of substitutions per site. All positions containing gaps and missing data were eliminated. Virus abbreviations are explained in the tables of member species and other viruses. Reproduced from: https://talk.ictvonline.org/ictv-reports/ictv_online_report/positive-sense-ssRNA-viruses/w/virgaviridae.

The tobamovirus members are divided into those having the origin of assembly in the MP coding region (subgroup 1) and those for which the origin of assembly is within the CP coding region (subgroup 2). This division is strongly supported by phylogenetic analysis that shows the tree with all available sequences to consist of two major branches, one corresponding exactly to subgroup 1 and the other to subgroup 2 (Fig. 1).

In these phylogenetic analyses, the closest neighbors that were not designated members of the tobamoviruses were a group of viruses typified by *Beet necrotic yellow vein virus*, thus defining the closest family of the *Tombusviridae* as the *Benyvirus* genus.

The assembly of evolutionary relationships in phylogenetic trees allows some thoughts on the evolution of virus genera. The tobamoviruses have sequence neighbors in other genera of ssRNA viruses. They include genera *Benyvirus* (as mentioned above and consisting of plant viruses) and *Orthohepevirus* (which are animal viruses). Most closely related to the genus *Tobamovirus* are the charaviruses which have been isolated from the algal genus *Chara* (Fig. 2).

Virus Structure and Composition

Tobamovirus virions are straight particles of approximately 18×300 nm with a central hollow core 4 nm in diameter (Fig. 3(A) and (B)). Virion composition is approximately 95% protein and 5% RNA. For TMV, approximately 2100 subunits of a single CP are arranged in a right-handed helix around a single genomic RNA molecule, with each subunit associated with three adjacent nucleotides. Protein-protein associations are the essential first event of virion assembly. Coat protein subunits assemble into several types of aggregates. Coat protein monomers and small heterogeneous aggregates of a few subunits are collectively referred to as 'A-protein'. The equilibrium between A-protein and larger aggregates is primarily dependent upon pH and ionic strength. Purified CP and viral RNA can assemble into

The green disks mark nodes with >0.9 SH support; two thirds of the nodes in the Orthohepevirus cluster have >0.9 SH support but, for clarity, are not marked.

infectious particles *in vitro*. Larger aggregates are disks composed of two individual stacked rings of CP subunits, and protohelicies. Protohelicies contain approximately 40 CP subunits arranged in a spiral around a central hollow core, similar to the arrangement within the virion. A sequence-specific stem-loop structure in the RNA, the origin of assembly (OAS), initiates encapsidation and prevents defective packaging that could result from multiple independent initiation events on a single RNA molecule. Virion assembly initiates as the primary loop of the OAS is threaded through a CP disk or protohelix with both ends of the RNA trailing from one side. The conformation of the CP protohelix changes as the RNA becomes embedded within the groove between the two layers of subunits. Elongation is bidirectional, proceeding rapidly toward the 5' end of the RNA as the RNA loop is extruded through the elongating virion and additional CP disks are added. There is disagreement about the mechanism of elongation toward the 3' terminus of the RNA, but it appears that this slower process involves the addition of smaller protein aggregates (Fig. 3(C)).

Sub-genomic mRNAs containing the OAS are encapsidated into shorter particles that are not required for infectivity. The OAS is located within the open reading frame (ORF) for the movement protein (MP) of most tobamoviruses. The level of accumulation of a particular sub-genomic mRNA containing the OAS determines the relative proportion of that particular virion species. Thus, all tobamovirus virion populations contain a small percentage of MP sub-genomic mRNAs (sgRNA). In some tobamoviruses, including Cucumber green mottle mosaic virus (CGMMV), Hibiscus latent Singapore virus (HLSV), Kyuri green mottle mosaic virus (KGMMV), Maracuja mosaic virus (MaMV), Sunn-hemp mosaic virus (SHMV), Zucchini green mottle mosaic virus (ZMoMV), and Cactus mild mottle virus (CMMoV), the OAS is located within the CP ORF. Thus, these so-called subgroup 2 tobamoviruses produce a significant proportion of small virions that contain CP sgRNA. Hybrid non-viral RNAs containing an OAS will also assemble with CP into virus-like particles of length proportional to that of the RNA.

Genome Organization

The genomes of tobamoviruses consist of one single-stranded positive-sense 6.3–6.8 kb RNA (Fig. 4). A methyl-guanosine cap at the 5' terminus, precedes a 55–75 nt AU-rich leader. The 3' end of the RNA can be folded into a series of pseudoknot structures including a tRNA-like terminus. The hibiscus-infecting tobamoviruses Hibiscus Latent Singapore virus (HLSV) and Hibiscus latent Fort Pierce virus (HLFPV) contain, in addition, a poly(A) stretch between the 3' end of the CP ORF and the tRNA-like structure. The tRNA-like termini can be amino-acylated *in vitro*, in most cases specifically accepting histidine. The 3' terminus of SHMV is an

exception, accepting valine and appears to have arisen by a recombination event between a tobamovirus and a tymovirus. RNA extracted from infected plant material can be used to make transcription plasmids, whose transcription will produce transcribable RNA molecules used to allow production of specific proteins in recipient plants.

Fig. 4 Tobamovirus genome organization and gene expression strategy. (a) Tobamovirus genome organization. ORFs designated as open boxes. Non-translated sequences designated as lines; positions of sub-genomic promoters are marked. (b) Non-structural proteins involved in tobamovirus replication. Functional domains shared with other viruses within the 'alphavirus supergroup' are designated as hatched boxes. (c) Sub-genomic mRNAs with 5' proximal ORF labeled. MP, movement protein; CP, coat protein; MT, methyl-transferase; HEL, helicase; POL, polymerase; MPsg, MP sub-genomic mRNA; CPsg, CP sub-genomic mRNA.

The four ORFs that are contained within all tobamovirus genomes (Fig. 4) correspond to the proteins found in infected tissue. Two overlapping ORFs begin at the 5' proximal start codon. Termination at the first in-frame stop codon produces a 125–130 kDa protein. A 180–190 kDa protein is produced by readthrough of this leaky termination codon approximately 5–10% of the time. The remaining proteins are expressed from individual 3' co-terminal sub-genomic mRNAs, from which only the 5' proximal ORF is expressed (Fig. 4). The next ORF encodes the 28–34 kDa movement protein, which has RNA-binding activity and is required for cell-to-cell movement. The 3' proximal ORF encodes a 17–18 kDa CP. A sub-genomic mRNA containing an ORF for a 54 kDa protein that encompasses the readthrough domain of the 180–190 kDa ORF has been isolated from infected tissue, although no protein has been detected.

Within the protein-coding regions of the genome, there are nt sequences that also function as cis-acting elements for sub-genomic mRNA synthesis, virion assembly, and replication. Gene expression from sub-genomic mRNAs is regulated both temporally and quantitatively. The MP is produced early and accumulates to low levels, whereas the CP is produced late and accumulates to high levels. The regulatory elements for sub-genomic mRNA synthesis are located on the genome-length complementary RNA overlapping the upstream ORF (Fig. 4). There is limited (40%) sequence identity between the TMV MP and CP sub-genomic promoters. The TMV MP sub-genomic promoter is located upstream of the MP ORF, flanking the transcription initiation site. Unlike the MP sub-genomic promoter, full activity of the CP sub-genomic promoter requires sequences within the CP ORF.

Viral Proteins

The tobamovirus 125–130/180–190 kDa proteins are involved in viral replication, gene expression, and movement. Both are contained in crude replicase preparations, and temperature-sensitive replication-deficient mutants map to these ORFs. The 125–130/180–190 kDa proteins contain two functional domains common to replicase proteins of many positive-stranded RNA plant and animal viruses (Fig. 4). The N-terminal domain has methyl-transferase and guanylyl-transferase activities associated with capping of viral RNA. The second common domain is a proposed helicase, based upon conserved sequence motifs. The readthrough domain of the 180–190 kDa protein has sequence motifs characteristic of RNA-dependent RNA polymerases (RdRp). Both proteins are necessary for efficient replication, although the TMV 126 kDa protein is dispensable for replication and gene expression in protoplasts. The 125–130 kDa protein (or sequences within this region) of the 180–190 kDa protein are required for cell-to-cell movement. Additionally, these multifunctional proteins are symptom determinants, as mutations in mild strains map to these ORFs.

The 28–34 kDa MP has a plasmodesmatal binding function associated with its C-terminus and a single-stranded nucleic acid-binding domain associated with the N-terminus. The MP–host interaction determines whether the virus can systemically infect some plant species. Although principally a structural protein, the CP is also involved in other host interactions. Coat protein is required for efficient long-distance movement of the virus. Coat protein is also a symptom determinant in some susceptible plant species and an elicitor of plant defense mechanisms in other plant species.

Interactions Between Viral and Host Proteins

Available evidence suggests that the interactions of viral proteins with host factors are important determinants of viral movement and host ranges. Amino acid substitutions in the movement protein and 125–130/180–190 kDa proteins can alter the movement function in different hosts. Some viruses, including tobamoviruses, can assist movement of other viruses that are incapable of

movement in a particular plant species. These interactions suggest that there are more precise associations of viral proteins with host factor(s) than with viral RNA. Additionally, precise CP–plant interactions are required for movement to distal positions within the plant. The helicase domain of the 130–190 kDa proteins elicits the N gene-mediated resistance in *N. glutinosa*.

Virus Replication

Virions or free viral RNA will infect plants or protoplasts. Because tobamoviruses have a genome consisting of messenger-sense RNA that is infectious, one of the first events is translation of the 5′ proximal ORFs to produce the proteins required for replication of the genomic RNA and transcription of sgRNAs. When virions are the infecting agent, the first event is thought to be co-translational disassembly, in which the CP subunits at the end of the virion surrounding the 5′ end of the RNA loosen, making the RNA available for translation. Ribosomes then associate with the RNA, and translation of the 126/183 kDa ORFs is thought to displace CP subunits from the viral RNA. After the formation of an active replicase complex, a complementary negative-strand RNA is synthesized from the genomic positive-strand RNA template. Negative-strand RNA serves as template for both genomic and sgRNAs. Negative-strand RNA synthesis ceases early in infection, while positive-strand RNA synthesis continues. This results in an asymmetric positive- to negative-strand RNA ratio. Early in infection, genomic RNA functions as template for negative-strand RNA synthesis and as mRNA for production of the 126/183 kDa proteins. Later in the infection cycle, most of the newly synthesized genomic RNA is encapsidated into virions. Sub-genomic mRNAs transcribed during infection function as mRNA for the 3′ ORFs. Within cells of an infected leaf, replication proceeds rapidly between approximately 16 and 96 h post infection within a cell, then ceases. Even though the infected cells become packed with virions, these cells remain metabolically active for long periods. During the early stages of infection of an individual cell, the infection spreads through plasmodesmatal connections to adjacent cells. This event requires the viral MP that modifies plasmodesmata to accommodate larger molecules and the 126/183 kDa proteins. Movement through plasmodesmata does not require the CP. A second function of the MP appears to be binding to the viral RNA to assist its movement through the small plasmodesmatal openings. The MP also appears to associate with the cytoskeleton. As the virus spreads from cell to cell throughout a leaf, it enters the phloem for rapid long-distance movement to other leaves and organs of the plant, a complex process that requires the CP.

The Cis-Acting Sequences

The 5′ non-translated region contains sequences that are required for replication. This region is an efficient translational leader. The 3′ non-translated region contains cis-acting sequences that are involved in replication. Certain deletions within the pseudoknots are not lethal, but result in reduced levels of replication. Exchange of 3′ non-translated elements between cloned tobamovirus species has resulted in some lethal and nonlethal hybrids, suggesting a requirement for sequence specificity and/or secondary structure. The 3′ non-translated region appears to be a translational enhancer, both in the viral genome and when fused to heterologous reporter mRNAs. Sequences encoding the internal ORFs for the MP and CP are dispensable for replication. Duplication of the sub-genomic promoters results in transcription of an additional new sub-genomic mRNA. Heterologous tobamovirus sub-genomic promoters inserted into the viral genome are recognized by the replicase complex and transcribed. Foreign sequences inserted behind tobamovirus sub-genomic mRNA promoters have been expressed to high levels in plants and protoplasts. Placement of the RNA sequence required for initiation of RNA encapsidation determines the size of the resulting virion accounting for the major differences in particle sizes within the tobamoviruses.

Satellite Tobacco Mosaic Virus

Satellite tobacco mosaic virus (STMV), a tobamovirus-dependent satellite virus, was isolated from *Nicotiana glauca* plants infected with Tobacco mild green mosaic virus (TMGMV). The STMV genome consists of one single-stranded positive-sense RNA of 1059 nt. The 240 3′ nt share approximately 65% sequence identity with TMGMV and TMV, contain pseudoknot structures, and have a tRNA-like terminus. No sequence similarity with any tobamovirus exists over the remainder of the genome. Two overlapping ORFs that are expressed in *in vitro* translation reactions are present in the genomic RNA of most STMV isolates. The 5′ proximal ORF encodes a 6.8 kDa protein that has not been detected *in vivo* and is not present in all STMV isolates. The second ORF encodes a 17.5 kDa CP that is not serologically related to any tobamovirus CP. The 17 nm icosahedral virions are composed of a single STMV genomic RNA encapsidated within 60 STMV CP subunits. Replication of natural populations of STMV is supported by other tobamoviruses, but at lower levels than with the natural helper virus, TMGMV. The host range of STMV parallels that of the helper virus.

Host Range and Symptomology

Tobamoviruses have a fairly large host range. All-in-all, dicotyledonous and monocotyledonous have been identified as hosts for the members of the 36 tobamovirus species and the 3 tentative members. TMV alone is known to infect members of nine plant

Fig. 5 Symptoms of Tobacco mosaic virus on tobacco White Burley (A. left) (Courtesy of Dominique Blancart, INRA, France) on tomato leaves (B. top right) and fruits (C. bottom right) (Courtesy T.A. Zitter, Vegetablemdonline, Cornell University, Ithaca, NY).

families, and at least 125 individual species, including tobacco, tomato, pepper (many members of the family Solanaceae), cucumbers, and a number of ornamental flowers, including orchids.

Many tobamoviruses infect plants producing a variety of virus-specific leaf pigment patterns, described by terms such as mosaics, mottles and yellows, depending on the virus tested. The first symptom of this virus disease is a light green coloration between the veins of young leaves. This is followed quickly by the development of a mosaic symptom of light and dark green areas on the leaves. "Rugosity" (crinkling of leaves) is observed in several cases of plant infection by tobamoviruses, as have other leaf deformations. These symptoms are more pronounced on younger leaves. TMV infection does not result in plant death, but if infection occurs early in the season, plants could be stunted. On tobacco, lower older leaves could be subject to "mosaic burn" especially during periods of hot and dry weather. In these cases, large dead areas develop in the leaves. This constitutes one of the most destructive phases of TMV infection. However, if TMV infects crops like grape and apple, it is almost symptomless. TMV over the last century has been known to cause a relatively stable production loss for tobacco of up to two percent per year in North Carolina, which is financially important for the tobacco industry.

TMV and ToMV are worldwide considered as major diseases for vegetable production (Fig. 5) and cause tremendous losses in many solanaceous crops, especially in greenhouses where a lot of movement and passages of workers happen.

Transmission

TMV and related tobamoviruses are transmissible to new plants only by contact of a plant with an inoculum. Therefore plants may become infected by rub inoculation of virions containing substances like Insect, animals, and humans visiting the fields. Plant infection begins when healthy plants contact virus contaminated sources. Particularly effective are rubbing with an aqueous suspension of virions. Animals moving through a field of infectious plants can, by brushing, pick up virions and transfer them to new host plants. Insects feeding on infected plants can also transmit tobamoviruses into their next host. Bee hives from an infected field can initiate an infection in another field. It is not clear whether the hive contains infectious particles and must itself be considered as the vector or not.

TMV is known as one of the most stable viruses. It has a very wide survival range. As long as the surrounding temperature remains below approximately 40°C, TMV can maintain its infectious capacity and all it needs is a host to infect. Greenhouses and botanical gardens provide the most favorable condition for TMV spreading, due to the high population density of possible hosts, the number of workers going through the plants and the constant temperature throughout the year.

One of the common and useful control methods for TMV is sanitation, which includes removing infected plants and washing hands and tools in between each planting. Crop rotation is also employed to avoid infected soil/seed beds for some time. As for any plant disease, looking for resistant varieties against TMV has been done for tobacco, tomato and other plants. Furthermore, the cross protection method has been used, whereby a more severe strain of TMV is inhibited by previously infecting the host plant with a mild strain of TMV. This method has been used for decades in the vegetable industry in Europe. Breeders have selected genes of resistance in tobacco, tomato and other crops, and those genes have been used in the industry. Precautionary measures taken in the use of tools and other objects has also been proven to decrease TMV spread in crops.

Glossary

Agroinfiltration Infiltration into air spaces within the plant leaves of cultured *Agrobacterium tumefaciens* bacteria leading to (usually) transient expression of functional genes or virus infectious clones in plants by transcription from a binary plasmid carried within the bacteria.

NM infection Infection of some plant species (primarily potato) by only the RNA1 molecule of TRV.

Initially erroneously thought to be “non-multiplying” hence NM.

Spraing Symptoms of dark flecking and arc-formation in tubers of some potato cultivars resulting from TRV infection.

Systemic infection Movement of virus from the point of inoculation to more distantly located leaves or roots via the plant vascular system (phloem).

Taxonomy and Characteristics

The genus *Tobravirus* is comprised of three species, the type species *Tobacco rattle virus* (TRV) together with *Pea early-browning virus* (PEBV) and *Pepper ringspot virus* (PepRSV), which was initially referred to as the CAM strain of TRV. The genus has been assigned to the *Virgaviridae* family. Tobraviruses have a genome of two, positive-sense, single-strand RNAs that are packaged separately into rod-shaped particles. In some situations, the larger genomic RNA (RNA1) can cause a systemic infection in the absence of the second, smaller RNA (RNA2) and without the formation of virus particles. Tobraviruses are transmitted between plants by root-feeding nematodes of the genera *Trichodorus* and *Paratrichodorus*, and in some plant species are also seed transmitted.

Virus Particle Production and Structure

Tobravirus RNA1 is encapsidated into the L (long) particle with a length of between 180 and 215 nm, depending on virus species, and RNA2 is encapsidated into S (short) particles which range in length from 46 to 115 nm, depending on virus isolate (Fig. 1). Both L and S particles have an apparent diameter of 20–23 nm, depending on the technique used to examine them. *In vitro* translation experiments using RNA extracted from purified virus preparations, as well as studies with the TRV SYM isolate, which has an unusual genome structure, showed that some, if not all, tobnavirus sub-genomic (sg)RNAs are also encapsidated, in particles of various lengths. The tobnaviruses encode a single coat protein (CP), molecules of which assemble in a helical arrangement around a central cavity with a diameter of 4–5 nm, and with a distance of 2.5 nm between successive turns of the helix. *In vitro* reconstitution experiments suggested that virus particle formation initiates at the 5′ end of the viral RNA, although the encapsidated sgRNAs do not carry the 5′ terminal part of the virus genomic RNAs. No specific “origin-of-assembly” sequence has been identified for any of the different tobnavirus RNAs. Peptide mapping showed that the major antigenic regions of the CP are, in descending order of strength, the C-terminal 20 amino acids (aa), 5 aa in the central region of the protein and 5 aa at the N-terminus. This and other spectroscopic analysis suggest that the N- and C-termini are exposed on the outer surface of the particle, while the central region is exposed in the central canal (where interactions of the CP with the viral RNA take place). The C-terminal domain appears to be unstructured and plays a role in interactions with other virus proteins that are involved in nematode transmission of the virus. Particularly with TRV, there is significant amino acid sequence difference between the CP of different virus isolates, resulting in many different serotypes of this virus.

M-Type and NM-Type Infections

In early studies with tobnaviruses (usually with TRV) the infectivity of fractionated and purified L and S particles was examined, showing that L particles were infectious (producing local and systemic symptoms on particular hosts) but that S particles were not. However, plants infected with L particles did not contain virus particles, whereas, plants infected with both L and S particles did contain (both) virus particles. This was explained by sequencing, which revealed that RNA1 encodes proteins for RNA replication and movement, whereas, RNA2 encodes the CP. Because infections with RNA1 do not produce virus particles they were very difficult to maintain by repeat inoculation of sap extracts, and were referred to as non-multiplying (NM-type) infections. Infections derived from both RNA1 and RNA2 and producing virus particles were easily passaged and were referred to as multiplying (M-type) infections. Subsequently it was found that extraction with phenol of RNA from NM-infected plants in fact produced highly infectious preparations.

Fig. 1 Electron micrograph of long and short particles of TRV isolate RH. Bar is 100 nm.

Early observations also suggested that NM-type infections caused more severe symptoms than M-type infections and moved only slowly up the plant, giving rise to the theory that un-encapsidated RNA1 could spread systemically only from cell to cell via plasmodesmata. However, experiments with TRV and PEBV carrying defined mutations in the CP gene demonstrated unequivocally that un-encapsidated virus RNAs moved very rapidly via the vascular system in both *Nicotiana benthamiana* and *N. clevelandii*. In addition, with wild type (encapsidated) virus systemic infection always included both RNA1 and RNA2 but with the (un-encapsidated) CP mutants RNA2 occasionally became separated from RNA1 and was not detected in some systemic leaves. One PEBV mutant carried only a small (28 aa) deletion at the C-terminus of the CP but did not produce virus particles or indeed any detectable CP in infected plants. Nevertheless, this mutant moved systemically as quickly as did wild type virus and in this case RNA2 did not become separated from RNA1. This suggests, perhaps, that some form of CP, which can be present at very low levels but is not incorporated into particles, enables the co-ordinated transport of RNA1 and RNA2 through the phloem.

In another study, plants were infected with TRV RNA1 and two types of RNA2, one wild type and the second encoding a CP in which the 15 aa at the C-terminus were replaced with 3 non-viral residues. Both RNA2 species were encapsidated by the CP that they encoded but neither appeared to be encapsidated by the CP from the other RNA2. Apparently, although RNA1 is encapsidated *in trans*, RNA2 is only encapsidated *in cis*. The mechanism for this is not known but may be linked to the role of CP in the co-ordinated systemic movement of RNA1 and RNA2.

Genome Structure and Expression

The viral RNAs have a 5' methylated guanosine cap. The 3' end of the RNAs is not polyadenylated but folds into a tRNA-like pseudoknot structure that, in contrast to some other virus RNAs, cannot be aminoacylated. RNA1 is from 6.8 to 7 kb in size, and RNA2 varies between isolates from 1.8 to 4.2 kb (**Fig. 2**). By February 2019 GenBank contained complete sequences for 17 TRV RNA1 and 36 TRV RNA2 molecules. However, for both PEBV and PepRSV only a single RNA1 and three RNA2 sequences were reported.

RNA Sequences

The larger RNA (RNA1) is highly conserved in nucleotide sequence between different isolates of the same virus (*e.g.*, 99% identity between RNA1 of TRV isolates SYM and ORY) but there is much less identity between isolates of the different tobnavirus species (*e.g.*, 62% identity between RNA1 of TRV isolate SYM and PEBV isolate SP5). The smaller RNA (RNA2) varies considerably both in terms of overall nucleotide sequence identity as well as protein coding capacity between isolates of the same virus, although phylogenetic analysis shows that the coat proteins (CPs) of the different tobnaviruses, which is encoded by RNA2, are more closely related to each other than to CPs from viruses in other genera. The tobnaviruses are most closely related to tobamoviruses, in terms of particle structure, overall gene organization and viral protein sequence homologies.

Depending on the specific virus and isolate, RNA1 has a 5' non-coding region (NCR) of between 126 and 202 nt, and a 3' NCR of 459 to 255 nt. RNA2 has a much larger 5' non-coding region (NCR) of between 470 and 710 nt, and a 3' NCR of 780 to 392 nt. There is almost no sequence homology between the 5' NCRs of the tobnaviruses, however, the 25 nt at the 3' terminus of the TRV

Fig. 2 Genome diagram and expression strategy of TRV isolates PpK20 and SYM. Open boxes denote virus genes. The solid lines above the RNA1 genes show the location of the two, overlapping replicase genes. The 134K protein contains methyltransferase (MT) and helicase (HEL) motifs. The C-terminal part of the 194K protein contains an RNA-dependent RNA polymerase (RDRP) motif. The asterisk denotes the 134K gene termination codon where readthrough translation to produce the 194K protein occurs. The movement protein (MP) gene is also known as the 29K or 1a gene. The cysteine-rich 16K gene is also known as the 1b gene. For RNA2, CP denotes the coat protein gene. N1 to N3 denote novel open reading frames present in isolate SYM RNA2. 2bΔ is a truncated 2b gene. The dashed lines beneath each RNA denote the 3' co-terminal sub-genomic RNAs that are known or suspected (?) to exist.

and PEBV RNAs are identical and there is 70% identity over the next 140 nt. Consequently, when recombinants were made between the RNA2 of TRV PpK20 and PEBV SP5, the RNA1-encoded replicase complex of both viruses could replicate RNA2 molecules carrying the 3' NCR from either virus. However, RNA2 carrying the TRV 5' NCR could only be replicated by a TRV RNA1, and RNA2 carrying the PEBV 5' NCR could only be replicated by a PEBV RNA1.

Expression of Virus Genes

The 5' proximal gene of RNA1, encoding viral replicase proteins, is expressed by direct translation of the genomic RNA. The two other RNA1-encoded genes (1a/29K and 1b/16K) are expressed from sgRNAs that start with the sequence AUA (within a conserved motif GCAUA) and that are co-terminal with the 3' end of the genomic RNA.

The 5' proximal gene of RNA2 of almost all tobnavirus isolates encodes the CP. However, the CP gene is located at least 470 nt downstream of the 5' terminus of RNA2, and this region contains numerous (at least six) AUG codons upstream of the translation initiation codon of the CP gene, that are inhibitory to CP expression. Experiments to delete parts of the 5' NCR of PEBV RNA2 showed that only a very small amount of CP is translated *in vitro* from full-length (genomic) RNA2 but that translation is increased 25-fold when the 5' NCR is removed. Thus, even though the CP gene is usually the 5' proximal gene on RNA2, it (and the other genes on RNA2), is expressed from a sgRNA. However, the CP gene of TRV SYM is located near to the 3' end of RNA2, downstream of other genes. The sgRNA for this CP is much shorter than genomic RNA2 and is encapsidated into a clearly identifiable VS (very short) virus particle.

A stem-loop sequence is found upstream of tobnavirus sgRNA start sites and is particularly conserved for the CP sgRNA. The introduction of mutations into this structure (8 bp stem, 4 nt loop) upstream of the PEBV CP gene showed that the stem-loop forms an essential part of the sgRNA promoter, and that the structure of the stem rather than its actual sequence is important for sgRNA synthesis *in planta*. The promoter regions for the TRV and PEBV CP genes could be used as a cassette and moved to other locations in RNA2 to express non-viral genes.

Recombination and Sequence Deletions in Tobnavirus RNAs

The large variation in the overall length of RNA2 from different tobnavirus isolates reflects the fact that most are recombinant molecules, where the 3' part of RNA2 has been replaced by sequences from the 3' part of RNA1. The recombination junction can occur at any position in RNA2 that is downstream of the CP gene, and the recombinant RNA2 molecule may retain none, some or even both of the other genes (2b and 2c) that might be considered RNA2-specific. The region of RNA1 that is transferred to RNA2 always includes the 3' NCR, often includes the 1b/16K/12K gene immediately upstream of the 3' NCR and may occasionally include part of the 1a/29K gene that is located upstream of the 1b gene. This means that many of these recombinant isolates carry two, probably both functional, copies of the 1b gene, one on RNA1 and the second on RNA2. In one study, a single *Alstroemeria* plant was found to contain seven different recombinant TRV RNA2 molecules, three with PEBV RNA1-like 3' NCR sequences and four with different TRV RNA1 3' coding and NCR sequences. The mechanism for such recombination is not known but is speculated to be caused by template switching by viral replicase from RNA1 to RNA2 during minus strand RNA synthesis. Sequences that resemble the 5' terminus of tobnavirus genomic RNAs (rich in A and U residues) are often found at or near the recombination junction, and conceivably could facilitate the recombination event. It is also not completely clear when tobnavirus recombination occurs, though the feeling is that repeated passage of virus by mechanical inoculation in glasshouse-grown plants, bypassing the nematode

transmission process, either encourages recombination or reduces selection against the survival of recombinants. Nevertheless, at least one known recombinant isolate, TRV PaY4, which was cloned after only a very limited period of multiplication in the glasshouse, did retain its ability to be nematode transmitted. When a TRV-infected potato plant was propagated by bud cuttings, a small (80 bp) deletion in RNA2 was detected only 5 days after planting, and by 33 days post planting an RNA2 was found lacking nearly 50% of its original sequence. By 55 days post planting no RNA2 could be detected in the plant, even though an RNA1 infection was maintained.

A different recombination process also occurs in which the CP and/or 2b gene in RNA2 of some TRV isolates appears to have been derived from PEBV. For this reason, serological analysis is not always successful in discriminating between the different tobaviruses. Attempts to reproduce this recombination by co-inoculating TRV and PEBV to plants in the glasshouse were not successful, suggesting that this may be only a rare occurrence, or may be stimulated by particular environmental conditions. Nevertheless, one report showed that 30% of the TRV isolates recovered from fields in the coastal bulb growing region in the Netherlands were TRV/PEBV recombinants.

For PepRSV RNA2, the three sequenced molecules all have RNA1-derived sequences at their 3' end and do not retain any 2b or 2c sequences. However, it is assumed in nature that this virus is nematode transmitted and, thus, that isolates carrying the 2b and 2c genes must exist.

Viral Proteins

RNA1

RNA1 encodes proteins for virus RNA replication and intra-plant movement (local and systemic). The 5' half of RNA1 encodes a large (134–141 kDa) protein that contains methyltransferase and helicase domains and is expected to be part of the viral replicase complex. Readthrough translation of the stop codon of this protein produces a larger protein (194–201 kDa) that contains motifs associated with RNA-dependent RNA polymerase proteins. *In vitro* translation experiments showed that the opal (UGA) translation termination codon of the TRV 134 kDa protein is suppressed by tRNAs that incorporate tryptophan or cysteine at this position. Downstream of the replicase genes is the 1a gene encoding a 29–30 kDa cell-to-cell movement protein (MP) belonging to the “30K” superfamily of plant virus movement proteins. Disruption of this gene prevents accumulation of TRV in inoculated leaves but can be overcome by co-inoculation with tobacco mosaic virus (TMV) or in transgenic plants expressing the TMV 30K movement protein. The C-terminal 1b gene encodes a 12 kDa (PEBV; PepRSV) or 16 kDa (TRV) cysteine-rich protein that is involved in seed transmission of PEBV in pea, and pathogenicity of TRV and PEBV. The TRV 16K protein is a suppressor of RNA silencing that is predominantly cytoplasmic but can also be found in the nucleus and nucleolus. The nuclear/nucleolar localization is important for the interaction of 16K with the plant protein coilin and the modulation of host plant anti-viral defense pathways. The TRV 16K protein is required to enable the virus to transiently enter the plant meristem. In *N. benthamiana* plants, a TRV 16K mutant virus does not enter the meristem, causes more severe infection symptoms and persists in the plant, whereas, with wild type TRV the plant recovers as the infection subsides and symptoms disappear. One study reported that the TRV 29K protein could also suppress RNA silencing when expressed during virus replication but not when expressed transiently via agroinfiltration. The PepRSV 12K protein also is a silencing suppressor and was found to enable potato virus X (PVX) to infect Arabidopsis when co-inoculated with PepRSV.

RNA2

RNA2 encodes proteins for virus particle formation and transmission by nematodes. Generally, the CP gene is the most 5' proximal gene on RNA2, even though it is expressed from a sgRNA rather than from the full-length, genomic RNA. As mentioned above TRV SYM has an unusual gene organization, with three potential genes located upstream of the CP gene. Several other TRV isolates from potato have also been identified in which the CP gene is preceded on RNA2 by novel genes that have no known function. Several studies have identified the CP as being involved in the nematode transmission process, and deletion of part of the C-terminal domain of the CP prevented the transmission of PEBV without affecting virus particle formation. Infectious, nematode-transmissible clones of three TRV isolates and one PEBV isolate have been constructed. In addition to the CP, these RNAs all carry two other genes encoding the 2b and 2c proteins, both of which (for PEBV) have been detected by western blotting in extracts of virus-infected plants. Mutation studies showed that the 2b gene is necessary for transmission of TRV and PEBV, whereas the 2c protein was only required for transmission of PEBV. This difference may reflect the different species of nematode that transmitted the particular virus isolates used in these studies, rather than a clear mechanistic difference between TRV and PEBV transmission. A further, small open reading frame, encoding a putative 9 kDa protein immediately downstream of and in-frame with the CP gene, is present in PEBV-TpA56 and TRV TpO1. For PEBV, mutation of this gene greatly reduced nematode transmission frequency, although the protein was not detected by western blotting.

The 2b proteins of the different tobavirus isolates share some amino acid sequence homology with each other, ranging from only 11% identity (TRV Umt1 v. TRV PaY4) to 99% identity (TRV Umt1 v. TRV OR2). They also range in size from 238 aa

(TRV PaY4) to 354 aa (TRV PpK20). The TRV PaY4 2b protein has been shown to act *in trans*, with nematode transmission of a 2b-mutant virus being complemented by co-infection with wild type virus. However, this appears to be isolate specific, as the TRV PaY4 2b mutant was complemented only by wild type TRV PaY4 and not by wild type TRV PpK20.

The 2b protein may influence nematode transmission by more than one mechanism. In a microscopy study of the roots of *N. benthamiana* plants infected by PEBV, large numbers of particles of the wild type virus were found in all regions of the root tip, which is where the vector nematodes preferentially feed, whereas virus particles of a mutant deleted for the 2b and 2c genes were present in roots only in much lower numbers. A similar enhancement was found in the efficiency of invasion of roots in *N. benthamiana*, as well as in leaves and roots of *Arabidopsis thaliana*, when TRV carrying the 2b gene was compared with TRV lacking the 2b gene.

Chemical analysis studies indicate that TRV infection increases the production of specific root volatiles and that TRV-infected plants are more attractive to vector nematodes. Furthermore, it seems that the TRV 2b gene plays some, as yet unclear, role in this process.

The 2b protein also physically interacts with the TRV CP (as examined by yeast two-hybrid (Y2H) analysis) and the virus particle (as examined by immuno-electron microscopy). One suggestion is that the 2b protein acts as a bridge to trap virus particles to specific sites of retention on the nematode esophageal cuticle. Aggregates of virus particles have been observed using the electron microscope to collect in this part of the nematode but the co-location of the 2b protein has not yet been demonstrated. It appears that interaction between the CP and 2b protein stabilizes the 2b protein, as in plants infected with wild type TRV PaY4, carrying both PaY4 CP and PaY42b genes, the 2b protein was detected by western blotting. However, with a recombinant TRV carrying the TRV PpK20 CP gene and the TRV PaY4 2b gene, the 2b protein could not be detected, possibly because these proteins from two different isolates cannot interact with one another.

Although the 2c protein is involved in transmission of PEBV, very little else is known about this protein. Amino acid sequence homologies between the 2c proteins of different TRV isolates range from almost none to over 95% identity. In a Y2H assay the TRV PpK20 2c protein interacted with the PpK20CP, and removal of the CP C-terminal flexible domain did not affect the interaction.

Tobraviruses as Gene Expression/Silencing Vectors

As RNA1 encodes all the proteins necessary for tobnavirus replication and movement, the RNA2 can be modified to carry non-viral sequences without greatly affecting virus infection. Expression vectors have been constructed from all three tobnaviruses, in which a duplicate CP promoter sequence is inserted downstream of the native CP gene followed by restriction sites to allow the cloning of other sequences. Together, the tobnaviruses can infect a wide range of plant species, often without causing particularly severe symptoms, features which increase their utility as expression vectors.

Plants infected with tobnaviruses often undergo a rapid recovery in which infection symptoms and virus levels fall dramatically, although the plants do not become free of virus, most particularly in the meristem regions. However, these plants have developed a strong resistance to further infection by the same virus, most likely by an RNA silencing-based mechanism. Although not well understood, it seems that tobnaviruses are potent triggers of RNA silencing but do not encode a strong silencing suppressor protein to counteract this host defense activity. A consequence of this is that when a host plant sequence is inserted into the virus genome, very strong silencing is initiated that targets expression of the host gene itself, a process known as virus-induced gene silencing (VIGS). TRV has become one of the most widely used VIGS vectors for studies of plant gene function in many different plant species, and PEBV is also a very effective VIGS vector for studies in pea.

Diseases Caused by Tobraviruses

TRV is found in many countries (Europe, North America, Japan, and Brazil) and has a particularly wide host range, infecting more than 100 species in nature and more than 400 species when tested in the glasshouse, although not all of these infections are systemic. As tobnaviruses are transmitted by soil-inhabiting nematodes, in the field infection may be limited to the roots. Weeds may play an important role in the maintenance and spread of tobnaviruses, with *Capsella bursa-pastoris*, *Senecio vulgaris*, *Stellaria media*, and *Viola arvensis* being the most commonly found (in the UK) weed hosts of TRV. Virus transmission in seed of these plants was also reported. Many crop plants are infected by TRV, the major diseases being those of potato and ornamental bulbs (narcissus, gladiolus, tulip, lily, and crocus). The symptoms of TRV infection in potato are the formation of arcs and flecks of brown corky tissue in the tuber which is referred to as spraing, and which can make the tuber unfit for sale. Both M-type and NM-type infections can produce spraing symptoms, which have been shown to be a hypersensitive (defense) response by the plant to the virus. It was thought that potato cultivars that did not show spraing symptoms were resistant to TRV, however, some infections can be symptomless in particular cultivars. Nevertheless, even these symptomless infections lead to significant reductions in tuber yield and tuber quality. Inclusion of tubers carrying symptomless infection could have major consequences for the production and distribution of seed potatoes (Fig. 3).

Fig. 3 Cross-section of a potato tuber showing spraing symptoms caused by TRV infection.

PEBV has been reported in several European countries (UK, Netherlands, Italy, Belgium, Sweden) as well as Algeria and Morocco. In the field it infects mainly legumes, including pea, faba bean, French bean, lupin, and alfalfa. Several weeds and other crop plants may be infected, although often only in the roots. Early studies referred to Broad bean yellow band virus (BBYBV) as a defined virus infecting various legumes. This is now known to be a distinct serotype of PEBV.

PepRSV has only been reported from Brazil, where it infects pepper, tomato, and artichoke, as well as local weed species.

Nomenclature

aa	Amino acid(s)	NASH	Nucleic acids spot hybridization
AGO	Argonaute protein	NBS-LRR	Nucleotide-binding site–leucine-rich repeat
amiRNA	Artificial microRNA	nm	Nanometer(s)
CAS	CRISPR-associated protein	NSP	Nuclear shuttle protein
CP	Coat protein or capsid protein	nt	Nucleotide(s)
CRISPR	Clustered regularly interspaced short palindromic repeats	NtRDR1	RNA-Dependent RNA Polymerase 1 from <i>N. tabacum</i>
dsRNA	Double-stranded ribonucleic acid	PCR	Polymerase chain reaction
ERF4	Ethylene response factor-4	PTGS	Post-transcriptional gene silencing
HR	Hypersensitive response	RDR6	RNA-dependent RNA polymerase 6
kb	Kilobases	SCR	Satellite conserved region
kDa	Kilo Daltons	SGS3	Suppressor of gene silencing 3
LAMP	Loop mediated amplification	siRNA	Small interfering RNA
LTP	Lipid transfer protein	SRAP	Sequence-related amplified polymorphism
MEAM1	Middle-East Asia minor I	sRNA	Small RNA
MED1	Mediterranean 1	ssDNA	Single-stranded deoxyribonucleic acid
miRNA	microRNA	TGS	Transcriptional gene silencing
MP	Movement protein	TrAP	Transcriptional activator protein
		VSR	Viral suppressor of RNA silencing

Glossary

Agro-inoculation A method enabling the transfer of DNA (such as cloned begomoviral molecules) into a host plant using *Agrobacterium tumefaciens*.

Rolling circle amplification A technique that allows amplification of circular DNA molecules (such as geminivirus genomes) with $\phi 29$ DNA polymerase and random primers under isothermal conditions.

Tolerance Defined as an interaction in which viruses accumulate to some degree without causing significant loss of vigor or fitness to their hosts.

Viral titer detection Radiolabelled nucleic acid molecules (begomoviral DNA) detection by using virus gene-specific labeled probe through Southern blot experiments.

Viruliferous whitefly A whitefly insect-vector population carrying an infectious begomoviral molecule.

Introduction

Tomato (*Solanum lycopersicum*) belongs to the family *Solanaceae* and is one of the most important vegetable crops grown in India. India is the second-largest tomato producing country in the world. Tomato is originating from America, probably in Mexico, and the center of diversification was in South America, probably in Peru.

Tomato leaf curl New Delhi virus (ToLCNDV) is a bipartite begomovirus species (genus *Begomovirus*, family *Geminiviridae*) and is a well-known plant DNA virus responsible for the disease called Tomato leaf curl disease (ToLCD). The epidemic might be linked to the increased population of viruliferous whitefly (*Bemisia tabaci*), the insect vector accountable for the spread of the pathogen of ToLCD, around the world including India. The first reported incidence of this disease was from northern India in 1948. The occurrence was also documented from central India during the 1950s, followed by disease incidence in tomato-growing regions of South India. The disease has since begun to emerge as a major threat to the production of the tomato crop in India. The total yield loss in tomato production by begomoviruses ranges from 18% to 100%. Factors such as age of the plant, viruliferous whitefly populations, aggressivity of the virus isolate and susceptibility of the tomato variety influence the production and may cause up to 100% yield loss. Tomato plants affected by the leaf curl disease exhibit typical symptoms of upward and downward leaf curling, leaf wrinkling, leaf blistering, vein clearing, distortion of leaves, and stunted plant growth that might result in a complete yield loss (Fig. 1).

Tomato leaf curl New Delhi virus (ToLCNDV) has been recorded in recent decades to cause devastating damage to tomato yield and other vegetable crop productions in the Indian agriculture sector, notably the disease in the northern part of India is more widespread. Using infected tissue samples from two separate locations, ToLCNDV was first sequenced and characterized in India in 1992. Until recently, the epidemic of ToLCNDV was confined to South-East Asian countries like India, Bangladesh, Thailand, Indonesia, Sri-Lanka and Pakistan. Recent reports are indicative of its presence in other countries such as Spain, Morocco, Italy, and

Fig. 1 Plants infected with ToLCNDV displaying typical yellow mosaic symptoms on leaves (A) tomato, (B) chilli, (C) egg plant (D) pumpkin, (E) zucchini plants, (F) An infected zucchini plants at the field. Molecular characterization and infectivity of a Tomato leaf curl New Delhi virus variant associated with newly emerging yellow mosaic disease of eggplant in India. *Virology Journal* 8 (1), 305.

Israel. However, ToLCNDV infectivity studies have not been performed yet on tomato, or in any other solanaceous or cucurbitaceous crops, in other countries and therefore the virus may be more widespread than anticipated.

Tomato Leaf Curl Disease and Virus Biodiversity on Tomato in the Indian Subcontinent

Members of the *Geminiviridae* family infect various monocots and dicots plants across the continents causing severe losses. These insect-transmissible geminiviruses are encapsulated in 2.7–5.2 kb twinned icosahedral particles with one or two (mono or bipartite) circular, non-enveloped single-stranded DNA (ssDNA) genomes. The members of the family *Geminiviridae* are further classified into nine genera such as *Becurtovirus*, *Begomovirus*, *Capulavirus*, *Curtovirus*, *Eragrovirus*, *Grablovirus*, *Mastrevirus*, *Topocuvirus*, and *Turncurtovirus* based on their genome organization, nucleotide sequence identities, and mode of insect transmission. Furthermore, *Begomovirus*, the largest genus of the family, comprises approximately 450 species of geminiviruses that infect many economically important crops, ornamental plants as well as weed plants, around the world, and they are all transmitted by whiteflies (*Bemisia tabaci* Genn).

As per the current International Committee on Virus Taxonomy (ICTV) recommendation and revision of taxonomy from the Xth ICTV Report, based on pairwise nucleotide alignment of the begomovirus genome sequences, the name of ToLCNDV covers in fact four geminivirus species. These four virus species are *Tomato leaf curl New Delhi virus* (ToLCNDV DNA-A and DNA-B, U15015 and U15017), *Tomato leaf curl New Delhi virus 2* (ToLCVNDV2, JQ897969), *Tomato leaf curl New Delhi virus 4* (ToLCVNDV4, KF551592) and *Tomato leaf curl New Delhi virus 5* (ToLCVNDV5, EF450316). The taxonomic classification also depends upon other factors such as relatedness with the major or minor parental sequences, the frequency and extent of recombination and the biological properties of the viruses. More than 280 ToLCNDV's complete full-length sequences have been reported till date at NCBI GenBank public database and out of that number at least 80 of them are reported from India infecting different crop plants but tomato. This virus seems to be very successful at invading space and new host niches, in the Indian subcontinent and also in several regions of the world. This information suggests that the emergence of ToLCNDV, which is already underway, could be the major agricultural threat for vegetable crops to India and other countries in the very near future.

Other begomovirus species such as *Tomato leaf curl Gujarat virus*, *Tomato leaf curl Bangalore virus*, *Tomato leaf curl Bangladesh virus*, *Tomato leaf curl Pune virus*, *Chilli leaf curl virus*, *Chilli leaf curl India virus*, *Pepper leaf curl Lahore virus*, *Ageratum enation virus*, and *Tobacco curly shoot virus* are also known to be associated with ToLCD, affecting the tomato production in the Indian subcontinent. The fact that ToLCD remains yet to be fully characterized even after 70 years of its first report, might be due to the diversity of the viruses causing the disease, broader host range, and high level of host-virus adaptability.

The full-length DNA sequence of an Indian isolate of ToLCNDV DNA-A (U15015) and DNA-B (U15017) was first elucidated in the early 1990s from a begomovirus infected tomato (*Solanum lycopersicum*) from New Delhi (hence the name of the virus species). The size of the ToLCNDV-[India: New Delhi: Severe:1992] DNA-A and DNA-B are 2739 and 2696 bp, respectively. Similarly, ToLCNDV2-[India: IANDS1:2011] (JQ897969) isolated from tomato in New Delhi, is 2735 bp, ToLCNDV4-[India: Junagadh: TC306:2011] (KF551592) isolated from tomato in Gujarat is 2739 bp and ToLCNDV5-[Bangladesh: cucumber:2006] (EF450316) isolated from *Cucumis sativus* (cucumber) infected leaves, from Bangladesh is 2738 bp. Although all of the above-mentioned ToLCNDV species are nearly similar in size, they share sequence-similarities of less than 90% and have been assigned so far into the four separate ToLCNDV species listed above.

Phylogeny and Molecular Diversity

Based on phylogeny, genome organization, and geographical distribution, begomoviruses are divided into two super groups namely the Old-World (OW) and New-World (NW) begomoviruses. Among the Old World viruses more than 57 begomovirus species have been identified on tomato and there are many other begomoviruses capable of infecting tomato as well. In the Indian subcontinent alone more than 17 species of begomoviruses have been identified from tomato. However, among all these viruses ToLCNDV has emerged in the recent years as the major virus infecting tomato in the subcontinent, as already mentioned four species bear the name of ToLCNDV and as of 2019, there was a total of 282 records at NCBI under the name of ToLCNDV. In other words there is a lot of begomovirus variability at large associated with the general syndrome of tomato leaf curl disease (ToLCD) in the world and in India particularly, but ToLCNDV has prevailed in the recent years on tomato and other crops in the Indian subcontinent.

When a detailed study comparison of all the 282 ToLCNDV isolates is performed, it is obvious that there are no strictly defined demarcation strains among all these isolates, with a few exception (see below) indicating that there have been a lot of recombination events among the individuals of this population. The pairwise multiple sequence alignment of all records bearing the name of ToLCNDV spans a great variability between 72% and 100%. Officially, four viruses, ToLCNDV (U15015), ToLCNDV2 (JQ897969), ToLCNDV4 (KF551592) and ToLCNDV5 (EF450316), have been identified by their sequence as representatives of four species. The original reference of ToLCNDV (U15015) scores 74% identity with ToLCNDV2, 87% with ToLCNDV5 and 89% with ToLCNDV4, however ToLCNDV2 is sharing 94% identity with the members of the species PeaLDV (identified since ToLCNDV2 was sequenced) indicating that ToLCNDV2 is an isolate of this species now called PeaLDV. For simplicity and clarity it is therefore proposed to drop the name ToLCNDV2. ToLCNDV5 is borderline and ToLCNDV4 is even more border line for species demarcation in the ToLCNDV population and it is believed it is best for the time being to consider them as unassigned isolates of the species ToLCNDV. In addition another isolate from *Capsicum annuum*, from New Delhi, is showing less than 75% identity with the original ToLCNDV reference (U15015), and 91% with members of the species ToLCNDV making it an isolate of that species. Finally a last isolate from a weed from Pakistan named ToLCNDV-[PK: Chiniot:ZI27: G11V4:12] (HG937523), is in fact 94–98% identical to PaLCV isolates and should be renamed as PaLCV-[PK: Chiniot:ZI27: G11V4:12].

Within the ToLCNDV cluster of the remaining 276 isolates spanning pairwise identities between 86% and 100%, one can recognize several sub-clusters that we recorded for simplicity from Strain A to P plus an additional 13 unassigned isolates that could each become a node for new strains when more samples will be sequenced. Among these 15 Strains some are very well defined with no overlap with others like the strain M and G for the Thai-Indonesian isolates, the strain C for the Spain-Italy isolates, or some Indian-Pakistan strains such as Strains L, A, B. The strains D, E, F, J, K, L and H are more overlapped and consequently more difficult to define. The original first isolate of ToLCNDV (U15015) belongs to the Strain H and it is the largest cluster within the ToLCNDV population with 86 isolates (Fig. 2).

Apparently for all the isolates collected so far there is some level of correlation with the geographical distribution for Europe and South East Asia, a correlation with the hosts has not been found. The same virus can infect a range of different host in the same region. Recently it is of interest to note that ToLCNDV has been identified on cotton (*Gossypium hirsutum*) in Pakistan along with the betasatellite Cotton leaf curl Multan betasatellite. These 8 cotton isolates cluster in the middle of the Strain H which is the cluster of the original ToLCNDV isolate (U15015).

Genome Organization and Function of Gene Products

Four families of ssDNA viruses (*Circoviridae*, *Parvoviridae*, *Spiraviridae* and *Geminiviridae*) infect a range of hosts such as plants, hyper-thermophilic archaeobacteria, vertebrates (mammals, birds, reptiles, fish) and invertebrates (arthropods, insects, crustacean, echinoderms). Among these four families, only the members of the family *Geminiviridae* are known to infect plants and the members are further categorized into nine genera and among them, only the genus *Begomovirus* contains either mono or bipartite genome.

ToLCNDV DNA-A comprises six open reading frames (ORFs), two in virion or sense strand (AV1/CP and AV2/Pre-coat) and four in complementary or antisense strand (AC1/Rep, AC2/Trap, AC3/Ren, and AC4). AC1 encodes a multifunctional and most conserved protein, Rep or replication-associated protein that initiates the viral replication. AC2 encodes Trap or transcriptional-activator protein and is involved in the modulation of transcriptional gene silencing (TGS) as well as in the post-transcriptional

Fig. 2 Maximum-likelihood dendrogram of ToLCNDV isolates, available at the NCBI GenBank database. Accession numbers for all these sequences are mentioned in the phylogenetic tree. The nucleotide sequences are aligned using Muscle algorithm with bootstrap values of 1000 replicates. The scale bar indicates the nucleotide substitution rate per site, estimated by the Jukes-Cantor model. The branches of the individuals belonging to the same cluster/strain have been collapsed for simplification. The orange color indicate isolates from India-Pakistan, dark blue indicates isolates from Iran, Green from Thailand, Indonesia, pink from Bangladesh, pale blue from Spain-Italy-Morocco. The Unassigned isolates are written in black. The putative other ToLCNDV species are written in red and their corrected name in dark blue (other species) or black (unassigned ToLCNDV isolates).

gene silencing (PTGS) pathways. The viral DNA replication is facilitated by another early transcriptional gene, AC3 or REn or replication enhancer protein. AC4 is the least conserved ORF and structurally overlapped with the AC1 ORF. The AC4 functions as an RNA-silencing suppressor and also the suppressor of PTGS pathway. AC4 encoded protein of ToLCNDV interacts with tomato AGO4. Non-functional mutant of ToLCNDV AC4 remained however infectious on solanaceous crops. The AV1 ORF encodes coat protein (CP) which is a highly conserved protein facilitating the assembly and packaging of the viral genome. ToLCNDVAV2 encoded pre-coat protein acts as host silencing suppressor and pathogenicity determinant.

In nature a severe and a mild strain of ToLCNDV (U15015 and U15016, respectively) isolated from tomato in India, the viruses were cloned and sequenced, and infectious clones were produced. It was demonstrated on *Nicotiana benthamiana* and *S. lycopersicum* plants, that the severe symptom was associated with the higher capacity of the Rep of the severe isolate to replicate components A and B. The infectivity data suggested that the asparagine at the 10th position (Asn10) of the Rep protein (AC1) of the severe strain specifically recognizes the 3rd base of the conserved iteron sequences although both severe and mild strain shares 94% pairwise nt identity on their Rep genes. It is therefore possible that in nature such mutation may be able to trans-replicate more molecules that could benefit the ToLCNDV DNA-A and DNA-B to impact its host range and ultimately its epidemiology.

Bipartite begomoviruses encode two additional ORFs (BV1 and BC1) in their DNA-B component. BV1 ORF encodes nuclear shuttle protein (NSP) in the virion or sense strand and BC1 encodes movement protein (MP) in the complementary or antisense strand of the viral genome. According to recent studies, transient overexpression of ToLCNDV-NSP induces the hypersensitive response (HR) or necrosis in *N. tabacum* plant. Similarly, ToLCNDV-BV1 N- or C-terminal mutant failed to show HR in *S. lycopersicum*. It is therefore postulated that the NSP may act as a symptom determinant and could serve as a silencing suppressor. Movement protein encoded by BC1 plays an important role in the intercellular movement of the viral DNA through the plasmodesmata.

In the context of the Indian subcontinent, one characteristic feature of ToLCNDV is its frequent association with either alpha- or betasatellites, despite being a bipartite begomovirus. Betasatellites are approximate ~1.5 kb in size and are half of the size of their helper DNA-A viruses, which are necessary for their replication and transportation. These molecules contain a satellite conserved region (SCR), an adenine-rich (A-rich) region and a single ORF in complementary sense strand named β C1. β C1 is a multi-functional protein that acts as a symptom-determinant in the host plant during begomoviral pathogenesis. Another category of ssDNA satellite molecules of ~1.5 kb was also identified and named as alphasatellites, which require a helper begomoviruses for inter- and intra-cellular movements, but is independent for replication. Alphasatellites were shown to be responsible for the reduced accumulation of betasatellite levels in begomovirus-beta satellite complexes and to act as a suppressor of RNA silencing.

Under laboratory conditions, maintenance of betasatellites (Cotton leaf curl Multan betasatellite, CLCuMB and Radish leaf curl betasatellite, RaLCuB) by ToLCNDV has been well documented. *N. benthamiana* plants agro-inoculated with ToLCNDV DNA-A contained lesser viral titer as compare to when co-inoculated with either CLCuMB or RaLCuB. Co-inoculated plants also exhibited severe symptoms indicating role of betasatellites in leaf curl disease development. However, it is important to note that DNA-A level was higher in plants co-inoculated with DNA-B as compared with betasatellites co-inoculated plants, which emphasized the important role of DNA-B over betasatellite in facilitating the movement of DNA-A. Furthermore, reduced level of CLCuMB in plants co-inoculated along with DNA-A and DNA-B as compared to DNA-A + CLCuMB indicates the role of DNA-B in modulating betasatellite levels in infected plants, precise mechanism of which is not yet known. Likewise, three alphasatellites were found to be associated with ToLCNDV in chilli, cotton and cucurbits plants during mixed infection (Table 1). However, the role of alphasatellites on ToLCNDV pathogenesis is yet to be ascertained (Fig. 3).

Synergism and Genetic Changes Leading to Begomovirus Emergence and Evolution

There are plenty of non-genetic based factors such as mixed infection, synergism, vector and vegetative dispersal, cultural practices and above all human movement of geminiviruses in new environments, which are promoting geminivirus infection in non-cultivated plants and/or other new cultivated crops. However, among all plant viruses, geminiviruses have a particularly high emergence potential because they can use each one or the combination of 4 important genetic-based mechanisms to rapidly change their genetic make-up and capacity, and thereby evolve within a concurrently changing environment to thrive and survive. In addition to having access to these molecular mechanisms, geminiviruses also enjoy a very high rate of multiplication, producing billions of new genomic molecules in a very short span of time, therefore they can afford a large fraction of non-functional molecules to explore many avenues at the same time. These four mechanisms are: the mutations, the recombination process, the pseudo-recombination and the capture of satellites.

Recent studies suggest that geminiviruses and nanoviruses, do show a high level of genetic variation and nucleotide substitution rate (10^{-3} – 10^{-4} substitution/site/year), and the mechanism is quite similar to RNA viruses. It is believed that these plant DNA viruses may use low-fidelity DNA polymerases for their genome replication which might lead to sequence variation in their genome fairly rapidly. Although, other factors which cause spontaneous mutation in the begomoviral genome (oxidation, transition, transversion, deamination and methylation of nitrogenous bases) might lead to their genetic variability and variation within the species as well.

Recombination plays an important role during geminivirus evolution and it can be achieved by two mechanisms, the rolling circle replication and the recombination dependent replication, which leads to the formation of complete new viral genomes. Studies suggest that inter and intra-species recombination events are very frequent in the geminivirus genomes. The impact of recombination has been studied and documented for several viruses such as the Tomato yellow leaf curl viruses, the East African cassava mosaic

Three alphasatellites have been reported to be associated with ToLCNDV DNA-A and other DNA-B in chili leaf curl disease (ChLCD) infected samples. These are: ChILCA (KF471051) with ToLCNDV (DNA-A, KU196750), associated with ChLCD from New Delhi; ChILCA (KF471052) with ToLCNDV (DNA-A and B, respectively, KP235540 and JN663871), associated with ChLCD, Himachal Pradesh and ChILCA (KF471046) with ToLCNDV (DNA-B, JN663848) associated with ChLCD, from Karnataka. In cucurbit plants, association of cucurbit yellow mosaic alphasatellite (CYMA, KT948075), ToLCNDV (DNA-A, HM98984; DNA-B, AM286435) and Papaya leaf curl betasatellite, KT948074). In addition, CLCuMA (LN845922, LN845923, LN845924, HG934391, HG934392, and HG934393) was also found to be associated with ToLCNDV A in cotton leaf curl disease (CuLCD) plants.

viruses and the Cotton leaf curl viruses. Although there has not been such detailed recombination analysis done for ToLCNDV, there is no reason to believe that ToLCNDV, does not benefit from the recombination strategy that many begomoviruses explored extensively. Furthermore, there are reports suggesting that ToLCNDV serves as a major parent donor helping in the production of other recombinant begomoviruses, such as Radish leaf curl virus (RaLCuV), Tomato leaf curl Rajasthan virus (ToLCRaV), Papaya leaf crumple virus (PaLCrV), Tomato leaf curl Patna virus (ToLCPaV) and Tomato leaf curl Palampur virus (ToLCPaV).

Interestingly pseudo-recombination or, re-assortment of genomic components of DNA-A and DNA-B for the bipartite begomoviruses results in exchange of the genetic materials similar but different to what's happening during intra-molecular recombination. It is similar because the bipartite begomovirus unit will acquire new proteins with new functions, but it is different because it is the whole set of two proteins acquired instantly and together with the DNA-B re-assortment. There is no creation of de novo chimeric proteins. This event has been reported to be more frequent for Old World begomoviruses, like that of between African cassava mosaic virus (ACMV) and East African Cassava mosaic virus (EACMV) but it has also been reported for New World begomoviruses such as the Pepper golden mosaic virus (PePGMV) and Pepper Huasteco yellow vein virus (PHYVV).

Fig. 3 Genome organization of ToLCNDV (DNA-A and DNA-B), a betasatellite and an alphasatellite. ToLCNDV is a bipartite geminivirus with components known as DNA-A and DNA-B. The proteins encoded by the components are indicated as the replication associated protein (Rep), the transcriptional activator protein (TrAP), the replication enhancer protein (REn), the C4 protein (C4), the coat protein (CP) and the V2 protein (V2) on the genomes of the DNA A component. The DNA-B component encodes the nuclear shuttle protein (NSP) and the movement protein (MP). A sequence conserved between the DNA-A and DNA-B components of bipartite begomoviruses is known as the conserved region (CR). The betasatellites have a single gene ($\beta C1$) in the complementary-sense and a region of sequence highly conserved between all betasatellites [known as the satellite conserved region (SCR)] and a region of sequence rich in adenine (A-rich). The alphasatellites have a single large protein (Rep) and also contain an A-rich sequence. For each component the conserved hairpin structure, containing the nonanucleotide sequence TAATATTAC (TAGTATTAC for most alphasatellites) within the loop structure, is shown at position zero.

Besides, in a laboratory-based experiment done with a pair of highly virulent pseudo-recombinant viruses between the DNA-A from Tomato leaf curl New Delhi virus (ToLCNDV, # U15015) and the DNA-B from Tomato leaf curl Gujarat virus DNA-B (ToLCGuV, # AY190291) it was shown that re-assortment was perfectly functional. This genetic re-assortment resulted in causing a very severe disease on tomato and other solanaceous crops. In those pseudo-recombinant infected plants, the levels of DNA-A and DNA-B were several-fold enhanced. Subsequently, these two molecules were observed under natural condition in the diverse agro-climatic regions of India in chilli, tomato and other solanaceous crops (Table 1). Furthermore, this association also resulted in the breakdown of geminivirus resistance in chilli indicating the relevance of fitness of viral molecules in the host plant. This super compatible integration of two different molecules in an innate condition may affect the host range and the epidemiology of the new virus disease.

The fourth possibility for genetic changes for begomoviruses is the capture of ssDNA satellites that are particularly abundant and variable (Table 1).

Host Range of ToLCNDV

The members of the ToLCNDV species share today a broad spectrum of host range, and they are known to infect 13 families of vegetable crops, flowering plants and weeds (Table 2). It is not known if the host range of ToLCNDV has effectively changed over

Table 2 List of plants, and their families, infected with ToLCNDV

Family	Crops
<i>Acanthaceae</i>	<i>Crossandra infundibuliformis</i>
<i>Amaranthaceae</i>	<i>Chenopodium album</i>
	<i>Convolvulus arvensis</i>
<i>Apiaceae</i>	<i>Daucus carota</i>
<i>Apocynaceae</i>	<i>Calotropisprocera</i>
	<i>Catharanthus roseus</i>
<i>Asteraceae</i>	<i>Calypocarpus vialis</i>
	<i>Chrysanthemum indicum</i>
	<i>Parthenium hysterophorus</i>
<i>Caricaceae</i>	<i>Carica papaya</i>
<i>Cucurbitaceae</i>	<i>Benincasa hispida</i>
	<i>Citrullus lanatus</i>
	<i>Coccinia grandis</i>
	<i>Cucumis melo</i>
	<i>Cucumis anguinus</i>
	<i>Cucumis sativus</i>

	<i>Nicotiana tabacum</i>
	<i>Solanum lycopersicum</i>
	<i>Solanum nigrum</i>
	<i>Solanum tuberosum</i>

time, but we can only take note that this virus has been isolated over time from a growing number of natural hosts, cotton being the last one. Because of the great capacity for this virus to capture other B components in mixed infections, acquiring thereby the capacity to move more efficiently both components in these hosts, or capturing satellites that could play an important role to suppress gene silencing of the hosts, or a combination of both strategies, it is possible that ToLCNDV has *de facto* expanded its host range.

It is also noticeable, that the new epidemic of ToLCNDV in Europe is mostly on cucurbitaceae, where the symptoms are very severe compared to tomato (Fig. 1). The sequence of both DNA-A and DNA-B components, although having both a large fraction of the typical ToLCNDV components, are novel and unique in the whole ToLCNDV molecular diversity for both components. A detail recombination study is needed to better characterize these molecules and understand the epidemiology of this new ToLCNDV strain.

Interestingly, co-infection of ToLCNDV is not limited to bipartite begomoviruses but it is also observed in association with monopartite begomoviruses such as Bhendi yellow vein mosaic virus (BYVMV), Chilli leaf curl virus (ChiLCV), Croton yellow vein mosaic virus (CYVMV), Squash leaf curl China virus (SLCCNV), Tomato leaf curl Ranchi virus (ToLCRnV) and Cotton leaf curl Kokhran virus (CLCKoV). A recent study demonstrates the presence of the monopartite begomovirus (ChiLCV) along with ToLCNDV (a bipartite begomovirus) and a betasatellite leading to a severe chilli leaf curl disease (ChiLCD). This interaction between the betasatellite and the geminiviruses led to a synergistic interaction benefitting the geminiviruses, and as a consequence enhancing the disease severity on chilli. Most surprisingly, in Pakistan, ToLCNDV (LN845962) was recently detected in cotton (*Gossypium hirsutum*) plants showing a typical cotton leaf curl disease. The association of ToLCNDV together with Cotton leaf curl Kokhran virus strain Burewala (CLCKoV-Bur) and Cotton leaf curl Multan betasatellite (CLCMuB) also indicate the possibility of synergistic interactions that might lead to the breakdown of CLCuD resistance in cotton.

Fig. 4 Geographical distribution of ToLCNDV isolates in the world. ToLCNDV has been isolated from thirteen different plant families that are shown in different colors. The dates for the world spread are roughly indicated with the color circles.

Transmission and Epidemiology

The occurrence of ToLCNDV in several countries in Asia, South East Asia, Middle East or Europe indicates that it is not limited by any geographical barrier and it must be efficiently transmitted by a range of whiteflies wherever the virus is present (Fig. 4).

ToLCNDV is transmitted by whiteflies (*Bemisia tabaci*, Genn., *Aleyrodidae*) under natural conditions and the role of seed transmission has not been evidenced yet but is most probably not relevant. Several biotypes/species of *B. tabaci* are reported to be transmitting begomoviruses to the Solanaceae, Cucurbitaceae, Malvaceae and many other crops. Middle-East Asia Minor I (MEAM1) (formally known as biotype B) is the most predominant whitefly population in India, especially in the southern part. Initially, the role of MEAM1 whiteflies as vector for transmission of begomoviruses onto solanaceous crops was not considered to be common, despite its presence along with other whitefly biotypes. There is a possibility that the invasive species population favors the emergence of a particular breed because of climate change. The other invasive species of whitefly known as Mediterranean 1 (MED1) (formerly known as biotype Q) was recently identified in Spain to cause ToLCNDV epidemics. This could be an alarming situation and a strategic plan to combat the disease needs to be developed. ToLCNDV has emerged as an Old World bipartite begomovirus that threatens several economically important crops in the world. The presence of ToLCNDV has been reported from thirteen different families of crop plants (Table 2) affected worldwide.

The epidemic outbreaks of ToLCNDV in India might be dependent on several factors such as the use of susceptible varieties for crop cultivation, the co-existence of different agro-climatic zones favoring the vector population survival, average rainfall, and the almost constant availability of the whitefly vector population that are swapping from one crop to another. Surprisingly, ToLCNDV is now more widespread in members of the Cucurbitaceae family as compared to Solanaceae or any other crops. In India, farmers generally cultivate cucurbits (bottle gourd, bitter gourd, muskmelon, squash, pumpkin and water melon) in almost every climatic season. The population of whitefly vector remains available throughout the year and the alternate hosts could act as a reservoir for ToLCNDV. In addition, the solanaceous crops such as tomato and chilli, are mostly grown in summer seasons. The higher temperature, relative humidity and availability of various whitefly biotypes/species may therefore provide an advantage for the insect vector to grow more and transmit the virus to several plant species.

Virus-Host Interactions

The geminiviruses utilize the host machinery to effectively function within the host. The plant-virus interplay differs along the spectrum of antagonism and mutualism. Begomoviruses have relatively small genomes that encode multitasking proteins required for the viral replication, encapsidation, transport, viral suppressor of RNA silencing and vector transmission. Many studies suggest plant viruses interact with many host factors and also manipulate several basic mechanisms of the hosts to perform their essential functions. As a counter defense mechanism, plants have developed several antiviral approaches. In a broader perspective, plants utilize resistance gene (R-gene) mediated defense and small non-coding RNA based defense mechanisms against the viral pathogen. In the next few paragraphs these two defense approaches have been discussed.

Small Non-Coding RNAs

Geminivirus infection triggers the production of two major classes of small non-coding RNA (sRNA): -small interfering RNAs (siRNAs) and -micro RNAs (miRNAs). These sRNA plays vital roles in the RNA silencing pathways and also control the expression of host genes. As an example, tomato plants infected with ToLCNDV showed upregulation of conserved miR319 and miR172 sRNA expression. These 21 nt long miRNAs play crucial role in regulating antiviral mechanism. Microarray data from ToLCNDV's agro-inoculated tomato plants suggested the differential regulation of miR398, miR399, miR162 and miR168. The miR162 and miR168 are known to regulate the expression of Dicer-like protein-1 (DCL1) and Argonaute 1 (AGO1) protein, respectively. The miR398 is involved in the abiotic-stress related response in plants, and it was observed that the level was higher when infected with the ToLCNDV. These data suggest ToLCNDV infection results in the transcriptional activation and suppression of specific miRNAs in host plant. Therefore, begomoviruses use this distressed gene expression to their purpose, resulting in building a suitable environment for survival inside the host cells. The functional characterization of siRNAs in susceptible, tolerant, and resistant tomato varieties during ToLCNDV infection also has been studied. In addition, the virus-specific siRNAs (Rep specific siRNAs) accumulation at 21 days post inoculation was higher in the tolerant varieties as compared to the susceptible varieties, as showed by northern blot hybridization experiments. The presence of virus specific siRNA were also noted in the systemic tomato leaves. These data further suggest that the virus specific siRNA might be inducing the gene silencing pathways in the tolerant varieties and it failed or is compromised to do so in the susceptible varieties. The higher ToLCNDV DNA-A level was effectively detected in the susceptible variety by Southern experiment.

Counter Defense RNA Silencing

Plants have an RNA silencing mechanism to control virus infection and as counter defense, viruses have viral suppressor of RNA silencing (VSRs) which regulate pathogenesis in the host cell. A bipartite begomovirus, such as ToLCNDV, encodes different proteins such as AC2/TraP, AC4, AV2/Pre-coat, and BV1/NSP to attenuate the gene silencing defense mechanism of the host by different means. ToLCNDV-AV2 inhibits the symptom remission on *N. tabacum* plants by blocking the RNA-Dependent RNA Polymerase 1 from *N. tabacum* (NtRDR1). NtRDR1 mediated antiviral silencing and the spread of virus specific siRNAs. Mutation in the AC4 ORF of ToLCNDV N50H (Asn position 50) led to the changes in β -sheet structure in SH3 domain resulting in affecting its ability to suppress the RNA silencing pathway. Although it was observed that these mutations do not affect the physical interaction of AC4 with AGO4. Hence, ToLCNDV-AC4 might have a role in targeting SH3 domain containing proteins to further modulate the begomoviral pathogenesis in a host cell.

Basal Level of Defense

It has been shown that ToLCNDV infections (in tomato and potato) can potentially induce the expression of plant-innate immunity and hormone signaling genes including ethylene-signaling genes such as ethylene response factor-4 (ERF4), WRKY, and NAC transcription factors. The ToLCNDV infection prompts the hypersensitivity response (HR) in the infected cells (in tomato plants) as a result of accumulation of higher reactive oxygen species (ROS) level. Oxidative burst at the infected sites eventually kills both the host and the invaded pathogen. Fortunately, during the course of evolution, a very efficient ROS-scavenging mechanism has also evolved in the plants.

Resistance Gene or R-Gene Mediated Defense

Plants have different strategies to combat the pathogens. One of the mechanisms of active plant defense is the resistance gene or R-gene mediated response. The R-gene can identify a specific effector molecule which is produced by the pathogen, and then initiate the HR, resulting in programmed cell death to inhibit the further amplification or spread of the pathogen. Over many decades, breeders have manipulated a likely host-target-loci that is liable with natural sources of resistance for viral infection. In some solanaceous (tomato) and cucurbitaceous plant genotypes, different resistance or tolerant genes have been identified to develop resistance against the ToLCNDV. Particularly, in tomato (wild type species) six TYLCV resistance loci (*Ty-1*, *Ty-2*, *Ty-3*, *Ty-4*, *Ty-5*, and *Ty-6*) have been identified, in which *Ty-2* alone failed to show resistance against ToLCNDV. Interestingly, the combination of *Ty-2*

(in homozygous or heterozygous condition) and *Ty-3* (heterozygous) through marker-assisted selection and breeding, is showing enhanced resistance against ToLCNDV and associated betasatellite. The loci *Ty-1* and *Ty-3* encode RNA-dependent RNA polymerase (RDR6). RDR6 is involved in the amplification of virus-specific siRNA which leads to the activation of the RNA silencing pathway. Similarly, ToLCNDV infection in solanaceous crop (*Capsicum annuum*, *N. tabacum*, *N. benthamiana* and *S. lycopersicum*) showed differential expression of defense-related genes such as Suppressor of Gene Silencing 3 (SGS3), RNA-Dependent RNA Polymerase 6 (RDR6) (genes which are involved in PTGS pathways), and the resistance gene (R-gene) such as nt-binding site and leucine-rich repeat (NBS-LRR), Lipid transfer protein (LTP) and pathogenesis-related (PR) genes.

A recent study suggests that some of the cultivated species of cucurbits (genus, *C. pepo*), wild type germplasm lines and F1-hybrid (subspecies *C. pepo* x *C. pepo* and subspecies *C. pepo* x *C. ovifera*) accessions exhibit resistance against ToLCNDV. Furthermore, the cucurbits accessions used for this study showed very mild symptoms, resulting in low viral titer even after several rounds of mechanical and whitefly inoculations. Similarly, inheritance study of *Luffa cylindrica* (sponge gourd) conducted during both rainy and spring seasons revealed presence of two sequence-related amplified polymorphism (SRAP) markers closely associated with dominant monogenic inheritance of ToLCNDV-resistance. Therefore these studies further indicate the existence of a genetic basis of resistance in cucurbit plants against ToLCNDV. The continuous evolution of geminiviruses and augmented host range, call for the need of resistance gene that should be investigated continuously to confer useful resistance against ToLCD to benefit farmers.

Diagnosis and Management

It is essential to confirm that a given disease is actually caused by a geminivirus, before developing a management program. Currently, the ToLCNDV detection is done by using polymerase chain reaction (PCR)-based amplification of the viral genome and loop mediated isothermal amplification assay (LAMP). Another recent technique is developed is the use of gold nanoparticle conjugated to a probe as biosensors. Furthermore, there are other methods of ToLCNDV detection such as coat protein specific antibody and non-radioactive nucleic acids spot hybridization (NASH) assay.

Because of its ability to infect and adapt in various plants, ToLCNDV is exceptionally tricky to manage and control. Some progress on the identification of resistance genes both in tomato and cucurbits is providing hopes that ToLCNDV could be controlled efficiently. Genetic engineering technique has been a key promising approach against the pathogen in a wide variety of crops around the world. One study suggests targeting of AV1/AV2 common overlapping regions by artificial miRNA (amiRNA), conferring tolerance against the ToLCNDV in transgenic tomato crops. However, as begomoviruses are continuously evolving it is very difficult to generate stable resistant or tolerant transgenic lines. The siRNA profiling in tomato and other solanaceous crop gives an idea about the novel resistance host genes. Their characterization can further provide a potential target to develop virus resistance/tolerance plants. Identifying the immune sources and implementing the specific gene in a targeted location to address the challenges of the specific virus, might lead to the sustainable management of the disease.

Various other approaches such as sense/antisense technology, RNAi techniques and application of double-stranded RNA (dsRNA) can also be used as potential method to develop resistance against the plant affecting begomoviruses. Recent advancement in the genetic manipulation of the DNA leads to the development of another system termed as clustered regularly interspaced short palindromic repeats-CRISPR associated 9 (CRISPER-Cas9) and is used to engineer broad-spectrum geminivirus resistance in plants. Other management practices like whitefly vector control, breeding of resistance varieties and micro-propagation of virus-free plants could be the alternative and complementary approaches to control ToLCNDV.

Glossary

Avirulence determinant Microorganism molecular patterns, e.g., a viral protein, that activate plant resistance proteins, inhibiting infection/virulence.

Circulative, propagative transmission Virus transmission process in which the virus circulates

through insect body and replicates in various tissue systems.

Processing bodies RNA-protein complexes located in the cytoplasm where RNA decay pathways occur.

Classification

Tomato spotted wilt orthotospovirus is the founding virus species in the genus *Orthotospovirus*, family *Tospoviridae*, order *Bunyavirales*. Tomato spotted wilt virus (TSWV) was first described in 1915 and was recognized as a bunyavirus in the 1990s based on virion morphology, genome sequence, and replication in the insect vector, thrips. TSWV was the first phytovirus classified as a bunyavirus. At present, there are 26 accepted species and 5 tentative species in the genus *Orthotospovirus* and there are three other phytovirus genera (*Tenuivirus*, *Emaravirus*, and *Coguvirus*) within different families in the order *Bunyavirales*.

Virion Structure

TSWV has the classic bunyavirus particle structure that is composed of a membrane that encapsulates the three genome segments (L, M, and S) that are coated in nucleocapsid (N) proteins. The genome is composed of negative-sense RNAs and the 5' and 3' ends of the viral RNAs are highly conserved and complementary. The complementary ends of the genome segments enable the formation of panhandle structures and these sequences serve as promoters for transcription of genes and genome replication. The N proteins arrange as asymmetric trimeric rings, creating an inner cavity where the viral RNAs bind. The virus particle also contains several copies of the L protein, an RNA-dependent RNA polymerase (RdRp), that is essential for infectivity of the virus upon delivery into the host plant or vector. The two glycoproteins, Gn and Gc, decorate the surface of the virion and are the attachment and entry proteins involved in the infection cycle in the insect vector (**Fig. 1**).

Among tospoviral proteins, the glycoproteins, and the N protein of TSWV and groundnut ringspot virus (GRSV) and the NSs have been predicted by folding prediction, and the native structure of the N protein was determined by crystallization, and the RNA binding sites were mapped in the simulated 3D structure. The N protein structure is composed of three main parts: N-terminal arm, C-terminal arm, and core domain. To form the trimeric ring, the N- and C-terminal arms of each N protein

Fig. 1 (Left) Virus particle diagram of TSWV. (Right) Transmission electron microscope picture of TSWV particles. The bar represents 100 nm. interact with the core domain of the other two adjacent proteins. The folding pattern consisted of a globular core shape containing two β -sheets and 12–17 α -helix, and two terminal chains corresponding to the N and the C termini exposed on the surface of the protein. The N protein structure has important aa for binding to RNA and protein folding such as R94/R95 and K183/Y184, which are mapped onto a charged surface cleft of the three-dimensional structure. Interestingly R95 is conserved among all orthotospoviruses and is consistently located in a α -helix.

Genome

The three negative-sense RNAs of TSWV encode six proteins on five genes, and some functions of each TSWV protein have been elucidated. The L protein (RdRp) works as a transcriptase, synthesizing mRNAs to be translated into functional proteins, and as a replicase, synthesizing new genomic RNAs which are then covered by N proteins. Interestingly, the L protein also snatches 5' capped ends from host mRNAs to cap-protect the viral mRNAs, the so-called 'cap-snatching' phenomenon. The L protein prefers cap-donors with multiple base complementarity to the viral RNA templates and seems to select host mRNAs which are destined for decapping in processing bodies (PBs). It has been shown that alterations in protein components of PBs, where mRNA decay pathways occur, interfere on TSWV cap-snatching and infection in *Arabidopsis* mutants.

The nucleoprotein (N) functions as a protective layer encapsidating the three viral genomic RNA segments, but also plays an important role in viral RNA transcription and replication. The N in the RNP complex interacts with the cytoplasmic tails of the glycoproteins which collectively form the mature virion or can interact with the NSm protein for cell to cell movement through the plasmodesmata.

The glycoproteins of TSWV are the viral determinants of insect transmission. The glycoproteins are encoded on single ORF and post-translationally cleaved into mature independent Gn and Gc proteins. The glycoproteins associate together and move from the ER to the Golgi where virus budding occurs. The glycoproteins in the Golgi form the external core that encapsidates the RNPs through interactions with the N protein and the cytoplasmic tails of the glycoproteins. The resulting double enveloped virion interacts with the endoplasmic reticulum cisternae, clustering several virions on vesicles. Gn also functions as an attachment protein for virus acquisition and is a determinant for virus transmissibility by thrips, while Gc is a viral fusion-like protein. The upstream sequence of Gn/Gc was found to contain promoter elements that are light and auxin inducible when expressed in *Arabidopsis*.

The NSm, a non-structural protein, serves as the cell to cell and long-distance movement protein (MP), through interaction with the N protein in the RNP complex. For cell to cell movement, the NSm forms tubular structures and modifies the size exclusion of the plasmodesmata with neighboring cells. Additionally, the NSm is associated with symptom expression and was shown to be an avirulence (avr) determinant in resistant plant varieties harboring the gene *Su-5b*.

The NSs, another non-structural protein, has been shown to serve as suppressor of antiviral RNA silencing in host plants and insect vector cells. The NSs also plays a major role in TSWV transmission by suppressing the biosynthesis of volatile monoterpenes, plant repellents of thrips. The NSs targets MYC transcription factors, regulators of the jasmonate(JA)-signaling pathway that controls the expression of *terpene synthase* genes. Therefore, TSWV-infected plants become more attractive to thrips, which favors virus acquisition by these insect vectors. The NSs is also associated with symptom development and supports systemic viral movement by interfering with antiviral RNA silencing in plants.

Fig. 2 The tomato spotted wilt virus transmission cycle. Thrips eggs are oviposited into plant tissue and within a few days the first instar larvae emerge. Virus acquisition occurs during the larval stages after which the virus persists in the vector and is passed transstadially to the adult. The pupal insects may occur in the soil or leaf tissue and these stages are nonfeeding. Adults emerge and may disperse widely. Only adult thrips (male and female) that acquired the virus during their larval stages can transmit tospoviruses. Used with permission from Rotenberg, D., Jacobson, A.L., Schneweis, D.J., Whitfield, A.E., 2015. Thrips transmission of tospoviruses. *Current Opinion in Virology* 15, 80–89.

Transmission

Insects in the order Thysanoptera are commonly called ‘thrips’ and they transmit TSWV and other orthotospoviruses in a circulative, propagative manner. There are over 7000 thrips species, but only nine species have been shown to transmit TSWV (*Frankliniella bispinosa*, *F. cephalica*, *F. fusca*, *F. gemina*, *F. intonsa*, *F. occidentalis*, *F. schultzei*, *Thrips setosus*, *T. tabaci*). All thrips species that transmit plant viruses are classified in the family Thripidae and they are phytophagous insects that feed in a piercing-sucking manner. Thrips feeding behaviors and high reproductive capacity make them efficient vectors of TSWV.

TSWV has a unique insect developmental-stage-dependent transmission cycle (Fig. 2). Virus is acquired when larval thrips feed on TSWV-infected tissue. As thrips mature, they lose their ability to become efficient vectors and adult thrips cannot effectively acquire virus and become virus transmitters. In the larval thrips that acquire TSWV, the virus disseminates from the initial site of infection, the midgut, to the salivary gland tissues. The pupal stages do not feed and thus do not acquire or inoculate virus. Both male and female adults are efficient virus transmitters and they can effectively disperse the virus over short and long distances. The small size of thrips makes them an efficient transport mechanism for viruses and thrips are often found in shipments of diverse types of plant materials.

The TSWV dissemination pathway in thrips has been described in detail. During larval thrips acquisition, the virus is ingested and enters the anterior midgut epithelial cells. This is the primary site of virus replication and virus infection appears to spread to surrounding cells. From the gut epithelial cells, virions traverse the basal membrane and basal labyrinth to then infect the muscle

cells surrounding the gut. Confocal and TEM immunolabeling studies have shown that the cells of the tubular salivary glands (TSG) contain detectable amounts of TSWV. The TSGs connect the midgut to the principal salivary glands and may serve as a conduit for virus movement between insect tissue systems. Alternatively, virus may move between gut tissues and principal salivary glands during the larval stage when these tissues are in direct contact. The principal salivary glands are the final site for virus replication prior to delivery of virus with feeding and salivation into the plant host. The extent of principal salivary gland infection has been shown to be associated with transmission efficiency. The virus abundance in larval thrips is positively correlated with infection status as adults and transmission efficiency. Interestingly, TSWV has not been found in the hemolymph of infected insects but this could be due to technical difficulties associated with virus detection in this small insect.

Epidemiology

Numerous experiments have confirmed that TSWV has a beneficial effect on *F. occidentalis*. The infection of several different plant hosts has resulted in faster developmental times for this species of vector. In addition, female thrips are attracted to the virus infected plants and this synergistic interaction facilitates transmission of the virus because larval thrips acquire TSWV. *F. occidentalis* is the most widespread vector of TSWV, but other vectors have regional importance and more varied interactions with the virus. For example, in the South-Eastern U.S. *F. fusca* is an important vector of TSWV to peanut but insect exposure to virus-infected peanuts negatively impacted vector development time. In addition to variation between TSWV-vector species interactions, there can be virus and insect isolate differences in interactions. Examination of TSWV-infected plants shows that they have higher levels of free amino acids and may have modified volatile organic compound profiles.

Pathogenesis

TSWV infects over a thousand plant species and infection results in significant yield losses for many agronomically important crops. Typical virus symptoms include stunting, wilting, and necrotic or chlorotic concentric spots on susceptible plants (Fig. 3). Many plants have an age-dependent susceptibility to TSWV. Physiological measurements of TSWV-infected peanut revealed that photosynthesis, transpiration, and water-use efficiency were significantly decreased in virus-affected plants. In TSWV-infected plants, the phytohormone salicylic acid is present at higher levels and SA-related genes are up-regulated indicating a plant defense response to virus infection. Several TSWV resistance genes have been identified and studied at the ecological and molecular level. In plants and insects, the TSWV NSs protein is a suppressor of RNA silencing and therefore a counter defense to one of the major antiviral responses in eukaryotic hosts. Also, the NSs of TSWV has been reported as an avr determinant in pepper (*Capsicum annuum*). This suggests an additional role for the NSs besides the well-defined RNAi suppressor activity. Likewise, it was recently suggested that the NSs of TSWV has a role in translation, and persistent infection and transmission by *F. occidentalis*. Furthermore, accumulation of high levels of NSs in the salivary glands of thrips could be indicative of NSs protein being co-injected into plants during thrips feeding. The NSs protein interferes with the RNA silencing response in plants by affinity for different types of dsRNA molecules.

Progress has been made in characterizing the thrips response to virus infection. There are diverse thrips-TSWV interactions that have been documented ranging from symbiotic to pathogenic and for the best characterized system, TSWV and *F. occidentalis*, the interaction is beneficial to the insect in most experiments. Gene expression analysis of western flower thrips, *F. occidentalis*, response to TSWV revealed that there is a developmental-stage-dependent transcriptome response to virus infection. The number and identity of responsive transcripts was unique to each thrips stage of development (larval, pupal, and adult). Only three sequences were differential in all life stages tested. The diverse response to virus infection over thrips development is likely due to the unique tissue tropism over the lifespan of the insect and dynamics of the virus replication cycle at the distinct infection stages. Similar experiments with TSWV-infected *F. fusca* yielded a greater number of differential transcripts but again a unique suite of responsive genes in larval, pupal, and adult thrips with only eight being responsive at all developmental stages.

Diagnosis

TSWV causes distinct foliar symptoms on some susceptible crops such as groundnut (peanut), potato, tobacco, and tomato that are of diagnostic value. Confirmatory, laboratory-based assays include ELISA-based serological test using antibodies specific to the N protein. The genome of several isolates of TSWV was sequenced and RT-PCR-based molecular detection methods are available.

Prevention

In case of perennials and vegetatively propagated plants and crops, virus can spread from infected mother plants through cuttings and tubers. Use of virus-free material is very effective in preventing disease outbreaks. TSWV is not seed-transmitted, and the primary source of infection in annual crops is mainly due to feeding by viruliferous thrips. Reducing yield losses due to TSWV infection is mainly through an integrated disease management (IDM) strategy that involves vector management by biological and

chemical means, cultural practices, and growing TSWV resistant cultivars. A set of IDM tactics was developed in peanut based on the relative importance of risk factors (TSWV Risk Index) that result in disease epidemics.

Plant Resistance

Several natural resistance sources have been reported to halt TSWV infection. Among them, only the tomato *Sw-5b* gene-mediated resistance has been deeply studied. Originally, the *Sw-5b* gene is from *Solanum peruvianum*, a wild species of tomato naturally occurring in northern Chile and southern Peru. The *Sw-5b* shares homology with other four *Sw-5* paralogs, named *Sw-5a*, *Sw-5c*, *Sw-5d*, and *Sw-5e*, encoding nucleotide-binding (N) leucine-rich repeat (L) receptors (R). The NLR proteins are usually activated by direct or indirect interaction with avr determinants, which eventually result in the appearance of necrotic spots on inoculated leaves, phenomenon known as hypersensitive cell death response (HR). Although many *Sw-5* paralogs and orthologs have been reported, only the *Sw-5b* protein has been proved to activate resistance to orthotospoviruses (Fig. 4). Due to its durability and broad-spectrum resistance, the *Sw-5b* gene has been introgressed into many commercial tomato cultivars, becoming the main natural resistance source against TSWV for this crop. This broad-spectrum resistance is not just observed for TSWV isolates, but also for orthotospoviruses classified in other species phylogenetically-related to TSWV.

The NSm protein is the cognate avr determinant of *Sw-5b*. Single expression of NSm in *Sw-5b*-transformed *N. benthamiana* and in *Sw-5b*-resistant tomato lines triggers HR in agro-infiltrated leaves. The recognition of NSm as avr occurs by its direct association with *Sw-5b*. Two domains of *Sw-5b*, NB-ARC and LRR, directly interact with NSm by recognizing an epitope of 21 aa, which is conserved among TSWV-related orthotospoviruses. Most NLR proteins, however, are thought to indirectly recognize pathogens since they monitor host proteins that are targeted and modified by avr determinants.

Fig. 4 *Sw-5b*-mediated resistance to TSWV in tomatoes. Although there are several *Sw-5* paralogs in tomato plants bred with *S. peruvianum*, only *Sw-5b* senses an epitope of 21 aa in NSm. This protein-protein interaction activates resistance to TSWV. Some point mutations in NSm, however, can turn resistance-inducing (RI) TSWV isolates into resistance-breaking (RB) isolates. The *Sw-5* proteins contain the domains SD (Solanaceae Domain), CC (Coiled-Coil), NB (Nucleotide-Binding), and LRR (Leucine-Rich-Repeat).

Other resistance sources to TSWV (*Sw-1a*, *Sw-1b*, *Sw-2*, *Sw-3*, *Sw-4*, *Sw-6*, and *Sw-7*), either recessive or dominant, have been reported and introgressed into commercial tomato cultivars. In comparison to *Sw-5b*, they commonly have a narrower-spectrum resistance against TSWV isolates and have not been characterized molecularly. In pepper, the *Tsw* gene activates resistance against TSWV isolates, inducing a clear HR on inoculated leaves. Besides some similarities with *Sw-5b*, the *Tsw*-mediated HR is triggered by the NSs protein of TSWV. Many other plant species and accessions have been reported to be resistant to TSWV isolates but, contrasting with plants harboring *Sw-5b* or *Tsw*, there is none or little genetic and molecular information available.

Overtime, the constant use of a monogenic resistance source on a virus population selects virus mutants that are not sensed by the resistance gene product or that suppress the resistance mechanism. In this context, TSWV resistance-breaking (RB) isolates have been reported for both *Sw-5b* and *Tsw* genes in tomato and pepper growing fields, respectively. Two aa substitutions in NSm proteins, C118Y or T120N, overcome *Sw-5b*-mediated resistance by TSWV isolates. A single mutation in the NSs protein, T104A, overcomes *Tsw*-mediated resistance. Evidences of reassortment events have also been reported for TSWV. This evolutionary mechanism is an additional advantage of TSWV in adapting to new plant hosts and thrips vectors, and from escaping selection pressures as resistance plant genes. The durability of a resistance gene in the field, nevertheless, can be spanned with proper management of resistant cultivars. Actions such as alternating resistant and susceptible cultivars or planting susceptible cultivars alongside production fields may reduce the selection and arising of RB isolates.

This is an update of H. Czosnek, Tomato Yellow Leaf Curl Virus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00717-2](https://doi.org/10.1016/B978-012374410-4.00717-2).

Glossary

Agroinoculation, agroinfection An alternative route for viral infection; the viral genome is cloned, usually as a head-to-tail dimer, in the T-DNA of *Agrobacterium tumefaciens* and is delivered to plants by inoculation.

Introgression Incorporation of chromosomal segments of wild tomato species in the domesticated tomato by crosses and selection; introgression lines are used to localize genes to the tomato chromosomes

Rolling circle Mechanism of replication followed by many viral DNA and by begomoviruses in particular.

Viruliferous whitefly Insect that has acquired virus from an infected plant and is ready to infect other host plants.

Whitefly Insect that belongs to the order *Homoptera*; they cause damage to plants by feeding and by vectoring plant viruses.

Introduction

Tomato yellow leaf curl virus (TYLCV) was coined in the late 1950s to describe a virus infecting tomato plants in the Middle East. TYLCV causes one of the most devastating diseases of tomato worldwide. The virus (genus *Begomovirus*, family *Geminiviridae*) is transmitted by the whitefly *Bemisia tabaci* (family *Aleyrodidae*, order *Hemiptera*) in circulative manner. The virus was isolated, cloned and sequenced in the late 1980s. It has a circular single-stranded DNA genomic molecule of 2787 nt encapsidated in a 20 × 30 nm geminate particle. The viral strand encodes four proteins while the viral complementary strand encodes two. The TYLCV genome replicates in host cell nuclei according to the rolling circle model. From the early 1960s, TYLCV has quickly spread from the Eastern Mediterranean Basin to the entire Middle East, Central and Southeast Asia, China, North and West Africa, Southeast Europe, the Caribbean islands, Southeast USA, the Southern Indian Ocean islands, Australia and Japan. Global warming may be instrumental to the expansion of the whitefly-transmitted virus to presently temperate regions. Sequence comparisons of TYLCV isolates from different regions revealed that the name TYLCV encompasses a complex of closely, as well as distantly, related begomovirus species affecting tomato. Over the last 40 years, TYLCVs have been the subject of numerous investigations, including epidemiology, phylogenetics, plant-virus-vector interactions, diagnosis, and breeding for resistance.

Classification and Taxonomy

TYLCV is a member of the genus *Begomovirus* of the family *Geminiviridae*. Begomoviruses are transmitted by the whitefly *Bemisia tabaci* (family *Aleyrodidae*, order *Hemiptera*). *B. tabaci* comprises many species (or biotypes), distinguished by their DNA sequence. Among them, the Middle East – Asia Minor 1 (MEAM1, or B) and the Mediterranean (MED, or Q) species are efficient vectors of TYLCV. TYLCV was isolated and its genome sequenced in the late 1980s. Begomoviruses have a genome either split between two circular single-stranded DNA (ssDNA) molecules of approximately 2700 nt each, named DNA A and DNA B (bipartite), or with a single genomic DNA A-like molecule (monopartite). TYLCVs are monopartite, except for two viruses from Thailand.

Sequence comparisons revealed that the name TYLCV encompasses a complex of closely, as well as distantly, related begomoviruses affecting tomato. Guidelines for the classification of begomoviruses state that genome-wide pairwise identities of 91% and 94% constitute the demarcation threshold between species and strains, respectively. Accordingly, TYLCVs are classified into several species and strains, listed in [Table 1](#) (updated as of January 2015). This classification is rendered more complicated by the discovery that recombination between different TYLCVs happens relatively frequently (see below). Additional begomoviruses that infect tomato cultures are described in other chapters. These viruses clearly differ from TYLCVs in the symptoms they induce on tomato, in their host range, and in their nucleotide sequence.

Virion Structure

Like all geminiviruses, TYLCV has a particle of twinned morphology of approximately 20 × 30 nm in size ([Fig. 1\(a\)](#)). The virus capsid consists of two joined, incomplete icosahedra, with a $T = 1$ surface lattice containing a total of 22 capsomeres each containing five units of a 260 amino acid coat protein (30.3 kDa). The geminate particle contains a single 2787 nt covalently closed genomic circular ssDNA molecule. A model of the structure of Ageratum yellow vein virus, obtained by cryo-EM at 3.3 Å, indicates that the DNA fills the entire available space within the particle.

Table 1 List of Tomato yellow leaf curl virus species, as of January 2015. Species names are shown in bold; isolate names are given in regular font. For species that do not have any known strains, only one isolate is listed, and that isolate is recognized as the “type” isolate. For species that have known strains, one isolate from each strain is shown, and the type isolate is the first one listed. Abbreviations are in the second column and the sequence accession numbers in the third

Genome

TYLCVs have a monopartite genome, except for two viruses from Thailand (Tomato yellow leaf curl Thailand virus – TYLCTHV, and Tomato yellow leaf curl Kanchanaburi virus – TYLCKaV), which have bipartite genomes.

Monopartite TYLCVs

A schematic drawing of the monopartite TYLCV genome is shown in Fig. 2. The TYLCV DNA-A-like viral genome encodes two large open reading frames (ORF) on the viral strand (V1 and V2), and four on the complementary strand (C1-C4). A 313 nt long intergenic region (IR) contains a 29 nt-long stem-loop structure with the conserved nanonucleotide TAAATATTAC, which is the origin of replication (Ori) of the virus. The IR also contains the promoters of the V1, V2, C1 and C4 genes.

Fig. 1 (a) Electron micrograph of TYLCV particles with twinned morphology of approximately 20×30 nm in size. (b) Non-infected and (b') TYLCV-infected tomato plant with young leaves showing typical yellowing and curling. (c) Tomato leaflet infested with *B. tabaci* whiteflies; insert: close up of adult whitefly.

Fig. 2 Genome organization of Tomato yellow leaf curl virus. The single-stranded virion DNA comprises 2787 nt. Open reading frames (ORFs) of virion-sense and complementary-sense strand polarity are designated (V) and (C), respectively. ORFs are represented by an arrow; numbers indicate first and last nucleotide of each ORF. V1 encodes the capsid protein (CP), V2 a movement protein, C1 the replication initiator protein (Rep), C2 a transcriptional activator protein (TrAp), C3 a replication enhancer protein (REn), and C4 a symptom and movement determinant. IR: intergenic region. The conserved inverted repeat flanking the conserved nanonucleotide sequence TAATATTAC is symbolized by a stem-loop; an arrow head indicates the cleaving position of Rep in the TAATATT/AC loop; A at the cutting site (/) is nucleotide number one, by definition.

- V1 encodes the capsid protein (CP). The CP is multifunctional: monomers interact to form the capsid. It has a nuclear localization signal (NLS) and it is able to shuttle the viral genomic DNA in and out of the nucleus. It is essential for infectivity, and it is the only viral protein recognized by the insect vector.
- V2 has properties analogous to those of a movement protein.
- C1 encodes the replication initiator protein (Rep). The functional protein is an oligomer. Rep recognizes the Ori and specifically cleaves the nanonucleotide TAATATTAC between nucleotides 7 and 8. Together with plant host polymerase(s) it initiates viral DNA replication according to the rolling circle model (RCR) (see paragraph "Life cycle").
- C2 encodes a transcription activator protein (TrAp). TrAp enhances transcription of the viral strand. It is able to bind to viral genomic DNA and possesses an NLS. In addition, it may act as silencing suppressors.
- C3 encodes the replication enhancer protein (REn). This protein interacts with itself to form oligomers. REn interacts with Rep and with cell-cycle associated host proteins to increase viral DNA amounts (genomic and double-stranded) in the infected plant.
- C4 encodes a protein not essential for infectivity but contributes to the spread of the virus in the plant and induction of symptoms. The protein may also act as a silencing suppressor.

Bipartite TYLCVs

Bipartite TYLCVs have a second genomic 2.7 kb component (coined DNA-B) with an ORF on the viral strand (BV1, encoding a nuclear shuttle protein) and another on the complementary strand (BC1, encoding a movement protein). Usually the DNA-A is enough to produce disease symptoms.

Satellite DNAs Associated With TYLCVs

Monopartite begomoviruses, among them TYLCVs, are often associated with alphasatellites or betasatellites, two types of 1.3 kb circular ssDNA molecules. The only sequence homology between begomovirus and satellite DNAs is the nanonucleotide within the conserved stem-loop structure of begomovirus genomes required for RCR. Alphasatellites encode a RCR initiator protein (Rep). Betasatellite encodes the multifunctional protein β C1, which may be involved in virus movement, and suppression of gene silencing. β C1 may also enhance symptoms, virus amounts and whitefly transmission. Begomoviruses assist satellites for replication, and encapsidation.

The introduction of betasatellites into western Mediterranean countries (*e.g.*, Jordan, Israel, Egypt, and Arabian Peninsula) where satellites have never been reported before is a potential threat to tomato cultivation. Indeed, it was reported that TYLCV and an associate betasatellite overcome resistance provided by the *Ty-1* gene.

TYLCV Genome Evolution

Epidemiological recordings and phylogenetic analyses suggest that TYLCVs most probably arose in the Middle East between the 1930s and 1950s. The global spread of TYLCV only began in the 1980s after the evolution of the TYLCV and TYLCV-Mild strains. Other centers of TYLCV evolution have been shown to occur, for example in Iran; however because this region is geographically isolated, these TYLCV variants have not spread.

TYLCV species often recombine. For example, TYLCV is a recombinant of TYLCV-Mild and Tomato leaf curl Karnataka virus (Table 1), while other begomoviruses from the Mediterranean basin are recombinants of TYLCV and TYLCV-Mild, and of TYLCV and Tomato yellow leaf curl Sardinia virus (TYLCSV). In Italy, Morocco and Spain, recombinations between TYLCV and TYLCSV occurred in tomato-growing areas. Recombinants were obtained in the laboratory by inoculating tomato plants with infective clones of two TYLCV species. Indeed, upon mixed infections, TYLCV and TYLCSV were detected in the same nucleus, a prerequisite for recombination.

Life Cycle

During feeding on the host plant, whiteflies introduce TYLCV in the phloem with their stylets. The particles penetrate phloem-associated cells. The viral ssDNA genome is uncoated in the cell cytoplasm. Then, it is imported into the nucleus where it is converted to dsDNA (or replicative form RF) thanks to the host cell replication machinery. The dsDNA acts as a substrate for transcription of the viral mRNAs, which are exported to the cytoplasm for translation of the viral proteins required in the nucleus to carry out further replication and transcription. In the nucleus, the RF is duplicated several times according to the RCR model. Several host factors are required for progression and termination of the RCR fork. The IR has a hairpin structure with repeat sequences known as 'iterons'.

Replication is initiated by Rep binding the iterons followed by the specific nicking of the nanonucleotide TAATATT/AC (/: site of nicking). Rep binds covalently at the 5' end of nick, while the 3' end is used for extension of RCR. REN oligomers interact with Rep and enhance its ATPase activity. TYLCV Rep also acts as DNA helicase and as a site-specific type I topoisomerase, unwinding the DNA double helix in the IR for progression of the RCR fork. One round of RCR gives rise to a full viral dsDNA RF along with a genome-long viral ssDNA, which is released following Rep nicking. The new viral strand ssDNA is circularized using the closing activity of Rep and can be further converted to several dsDNA RF that serve as template for transcription/replication. From each RF molecule, several viral ssDNAs are produced. The replication process stops, perhaps with the increasing concentration of viral CP. The ssDNAs are either packaged in virions, or are transported out of the cell as nucleo-protein complexes. With the help of MP encoded by the virus, the transport occurs through the plasmodesmata into the neighboring cells, eventually leading to the long-distance spread within the host plant using its vascular system.

Geminiviruses activate the host cell replication machinery for their own multiplication. Several plant factors interact with viral Rep and Ren to modulate viral DNA replication. The retinoblastoma related (RBR) protein, a plant homolog of the tumor suppressor retinoblastoma (pRb), controls the plant cells entry into S phase. RBR interacts with Rep, inducing the accumulation of both viral and host DNA. Rep is also associated with other host factors such as the Replication factor C (RFC) that helps generate a primer with 3'-OH terminus during initiation of DNA replication.

Posttranslational modification processes like acetylation and sumoylation regulate various cellular processes, such as nuclear-cytosolic transport, transcriptional regulation, apoptosis, protein stability, response to stress, and progression through the cell cycle. As such, they are targets of viruses, which aim at modifying the host environment. The viral Rep interacts with the host sumoylation enzyme, alters sumoylation of the host Proliferative cell nuclear antigen (PCNA) that acts as a cofactor for DNA polymerase δ , which

enhances processing of the leading strand DNA synthesis during replication. Rep activity is reduced following the interaction with PCNA. In contrast, other host proteins may enhance the replication by Rep. For example, the host ssDNA-binding protein, Replication protein A (RPA) 32 kDa subunit (RPA32) directly interacts with the Rep C-terminus. RPA32 modulates the functions of Rep by enhancing its ATPase and decreasing its nicking and closing activities.

The 3-D configuration of the genomic viral DNA may by itself guide the assembly of the particle from a pool of CP monomers. Once in the phloem, TYLCV virions can be picked up by whiteflies, circulate in the insect and may be used to infect new plants during feeding.

Hosts

The domesticated tomato *Solanum lycopersicum* is the primary host of TYLCV. Most of the wild tomato species include accessions that either are symptomless carriers or are immune to the virus. In addition to tomato, several cultivated plants are hosts of TYLCV and present severe symptoms upon whitefly-mediated inoculation: bean (*Phaseolus vulgaris*), petunia (*Petunia hybrida*), and lisianthus (*Eustoma grandiflorum*). Pepper (*Capsicum annuum*) is a symptomless host of the virus. Weeds, such as *Datura stramonium* and *Cynanchum acutum*, present distinct symptoms while others, such as *Malva parviflora*, are symptomless carriers. Plants used to rear whiteflies in the laboratory, such as cotton (*Gossypium hirsutum*) and eggplant (*Solanum melongena*), are immune to TYLCV. Experimental hosts of the virus include jimsonweed (*Datura stramonium*) and Arabidopsis (*Arabidopsis thaliana*). Some plants, such as *Nicotiana benthamiana* and *N. tabacum*, which are recalcitrant to whitefly-mediated inoculation, may be inoculated with infectious TYLCV DNA clones using agroinoculation or DNA-coated micro-projectile bombardment.

Epidemiology

Geographical Distribution and Spread

The name Tomato yellow leaf curl virus (TYLCV) was coined in the early 1960s to describe a virus transmitted by the whitefly *B. tabaci* that affected tomato cultures in Israel. At the time, diagnosis of TYLCV was based essentially on symptom observation: border curling, yellowing and thickening of leaves, and plant growth stunting.

The whitefly *B. tabaci*, has been instrumental in the worldwide spread of TYLCV. Whiteflies can fly for several km. They are very resilient and their eggs can sustain low temperatures. Global warming may facilitate the expansion of *B. tabaci* to presently cold regions devoted of whiteflies.

Perennial weeds such as *Cynanchum acutum* and the annual weed *Malva parviflora* constitute TYLCV reservoirs in fields, especially outside crop growing seasons. A recent report claimed that TYLCV from South Korea is also transmitted through tomato seeds. This report needs to be confirmed.

DNA sequencing has become the tool of choice allowing accurate identification of TYLCV isolates and their relationship with others. The virus first reported in Israel in the 1960s was isolated and sequenced in the late 1980s. Another, different, TYLCV species from Israel was coined TYLCV Mild and was sequenced in the early 1990s. TYLCV was reported in the mid and late 1970s in Cyprus, Jordan, and Lebanon. It was identified in Egypt and Turkey in the early 1980s. The virus has spread to Turkey, Iran and the Asian republics of the former USSR, and to the Arabian Peninsula during the mid-late 1990s. Two TYLCV isolates closely related to the Middle Eastern virus were described in Japan in 1996, from where they spread to South Korea where TYLCV was reported in 2008. In China, TYLCV isolates were identified in Shanghai in 2006 and have rapidly spread since to most of the country, thanks to invasive whitefly species. A local species was coined Tomato yellow leaf curl China virus (TYLCCNV). It was shown to possess a betasatellite. In the early 1990s two virus isolates belonging to a new species related to the Middle Eastern TYLCV, named Tomato yellow leaf curl Sardinia virus (TYLCSV) were identified in Sardinia and in Sicily, Italy. The Sardinian isolate was discovered in Spain in the early 1990s. By the mid 1990s the Middle Eastern TYLCV was found in Portugal and in Spain. In the latter country, it tended to displace the previously established Italian virus. Recombinants between the two viruses are not rare. TYLCV has invaded North Africa, possibly from Spain and Italy. In Morocco and Tunisia, both the Italian and the Middle Eastern strain were discovered in the early 2000s. TYLCV appeared in Southern France in 1999. In 2000, the Middle Eastern strain of TYLCV was identified in Greece. In East Africa, TYLCV was present in Sudan as early as the late 1970s. In Tanzania, a virus distinct from the Mediterranean isolates was identified. In the Réunion Island, TYLCV was detected in the late 1990s. The Middle Eastern strain of TYLCV has appeared in the Western Hemisphere in the mid 1990s in the Caribbean Islands, first in the Dominican Republic, then Cuba, Jamaica, Puerto Rico and the Bahamas. From there, the virus has reached the USA, identified first in Virginia in the late 1990s, then in Florida, Georgia, Louisiana, North Carolina and Mississippi. TYLCV was reported in the late 2000s in several regions of Mexico. In 2006, TYLCV was reported in the Brisbane area, Australia, likely imported from Japan.

Hence, TYLCV has spread extremely fast and at present, constitutes a major limiting factor to tomato cultivation, worldwide. In many regions, the invading Mediterranean strain of TYLCV co-exists with local TYLCV strains but in several cases, it has almost replaced them, as in Southern Spain. Several introduction of TYLCV seemed to have occurred to the American/Caribbean region from the East-Asian, Australian, and Western Mediterranean regions, and several introductions of TYLCV to the East-Asian region

from the Eastern Mediterranean and Western Mediterranean regions. The detection of TYLCSV in Jordan and in Israel, indicate that TYLCV spread may occur from the Western to the Eastern Mediterranean region and to other parts of the world.

TYLCV-Whitefly Vector Relationship

Path of the virus in the insect

Like all begomoviruses, TYLCV follows a well-defined path in its *B. tabaci* vector (**Fig. 1(c)**). Whiteflies feed when their stylets reach the virus-rich phloem of infected leaves. TYLCV can be detected in the insect head approximately 10 min after the beginning of feeding (acquisition access period AAP) on infected tomato. From the esophagus, the virus reaches the midgut where it can be detected about 30 min after it was first found in the head. At this point, some of the virus might be excreted through the hindgut and rectum (honeydew). The virus reaches the hemolymph 30 min after it was first detected in the midgut, 90 min after the beginning of the AAP. The crossing of the gut is likely to be an active process involving specialized, unknown, receptors. To avoid degradation in the hemolymph, TYLCV interacts with a GroEL-like chaperonin produced by the insect endosymbiotic bacteria and excreted in the hemolymph. TYLCV can be detected in the salivary glands approximately 5.5 h after it was first detected in the hemolymph, 7 h after the beginning of the AAP, approximately 1 h before the insects are able to infect tomato plants. Once the virus reaches the salivary gland, crossing several cell walls that may constitute selective receptor-mediated barriers, it is almost immediately excreted into the salivary pump and from there into the plant, together with the saliva. TYLCV transits with the same velocity in males and females. The virus capsid is the only structure recognized by the would-be receptors in the gut and salivary gland barriers, and by endosymbiotic GroEL.

Retention of the virus in the insect vector

Once TYLCV is acquired, viral DNA remains associated with *B. tabaci* for the entire adult life of the insect, although infectivity decreases with time, but not entirely. TYLCV concentrates mainly in the filter chamber and the midgut. Various TYLCV isolates may present different parameters of interactions with their whitefly host.

TYLCV, TYLCSV and TYLCCNV were detected with very low incidence in eggs and in the adult progeny of viruliferous whiteflies. The CP was shown to be essential for virus invasion of the female reproductive system of *B. tabaci* B and Q. Entry of TYLCV into eggs developing in ovaries is mediated by the interaction of CP with vitellogenin. The CP region necessary for crossing the gut into the hemolymph is also necessary for salivary glands and ovaries penetration. TYLCV and TYLCCNV were shown to be transmitted with very low frequency among whiteflies during mating.

Replication of the virus in the insect vector

Replication of begomoviruses in their whitefly vector is a controversial issue. To prove, or disprove replication, viral DNA (genomic and RF) and CP amounts were usually appraised in whiteflies following a short AAP on TYLCV-infected plants and transfer to a non-host such as cotton, or on an artificial diet.

In one set of experiments involving TYLCV, TYLCCNV and TYLCV-Mild, the amount of viral genomic DNA and its complementary strand, and of viral transcripts (especially from the viral genome complementary strand) increased with time, and then decreased, as measured by qPCR. These molecules were visualized by FISH in the midgut epithelial cell nuclei and in cells of the salivary glands. *In situ* fluorescent immunodetection and western blots showed increases in CP amounts. These results supported TYLCV replication in whiteflies.

In another set of experiments, TYLCV and TYLCV-Mild did not accumulate following the end of the AAP. Moreover, whiteflies fed with purified TYLCV and TYLCV-Mild virions through membranes did not show any evidence of replication. These results led to the conclusion that TYLCV did not replicate in its vector.

Effects of TYLCV on life expectancy and fertility of the whitefly vector

Several studies indicated direct and/or indirect influence of begomoviruses on *B. tabaci*, which can be detrimental, neutral or beneficial, depending on the virus-whitefly-plant combinations. In experiments performed in China, TYLCV infection of tomato indirectly improved the overall performance (higher survival, greater fecundity, shorter development time) of the *B. tabaci* Q biotype, whereas it reduced the overall performance of the B biotype. Other studies performed in China indicated TYLCV has little effect on the reproduction and development of Q whiteflies. In Israel, 3-days-old B whiteflies raised on eggplants (a TYLCV non-host) following a 48 h AAP on TYLCV-infected tomato plants showed a significant reduction in their life expectancy and a ~50% decrease in the number of eggs laid. TYLCCNV also reduces female longevity and fecundity of B whiteflies. The negative impact of TYLCCNV was explained by TYLCCNV's suppression of the whitefly immune responses by down-regulation genes in the Toll-like signaling and mitogen-activated protein kinase (MAPK) pathways. The deleterious effects on its whitefly vector, in addition to the invasion of the reproductive system, suggest that TYLCV has some features reminiscent of an insect.

Pathogenesis

In the field, it is common that tomato seedlings are infected immediately after planting. Infection is always associated with large amounts of whiteflies (**Fig. 1(c)**). Young leaves and shoot apices are the best targets for whitefly-mediated virus inoculation. In the field as well as the greenhouse, symptoms of TYLCV infection include severe stunting, reduction of leaf size, upward cupping/curling of leaves, chlorosis on leaves and flowers, and reduction of fruit production (**Fig. 1(b)** and **(b')**). TYLCV can cause up to 90%–100% yield loss. In nethouses and greenhouses, infected plants are found near the (double) doors and close to ventilation openings.

Diagnosis

Symptom observation

The first step of diagnosis is examining symptoms, and inspecting the lower leaf surface for the presence of whiteflies. Early symptoms include yellowing, curling and thickening of young leaves. Later on, the plant becomes stunted and presents a bushy-like growth.

Microscopy

Light microscope observation of leaves infected with geminiviruses, including TYLCV, reveals characteristic large blue-violet nuclear inclusions following azure-A staining. Typical geminate particles can be observed with the transmission electron microscope (TEM) following virion purification. The virions can be decorated with anti-CP antibodies (immune electron microscopy) prior to observation under TEM. Particles can be TEM-observed in thin sections of infected leaves, using CP antisera and immuno-gold labeling. These methods are not of practical use for the detection of the virus in large numbers of plant samples.

Immunodetection

Immunodetection of TYLCV includes ELISA and western blots. Particles are also visualized in preparations of plant and insect tissues using labeled antibodies. However, the antibodies raised against the viral CP (overexpressed in bacteria or from purified virions) are usually unable to distinguish TYLCV from closely related begomoviruses, and unable to discriminate between TYLCV species and strains.

Nucleic acid hybridization

TYLCV genomic DNA and replicative dsDNA are readily detectable in DNA isolated from plants subjected to Southern blot hybridization, using a labeled DNA probe (preferably not radioactive). Similarly, TYLCV genomic DNA is detectable in viruliferous whiteflies.

TYLCV DNA sequences are detected by hybridization of infected plant tissues and viruliferous whiteflies squashed onto a nylon membrane (squash-blot, or tissue-blot) with a labeled specific DNA probe. No treatment of the sample is necessary prior to squashing and hybridization. Large numbers of plant and insect samples can be collected from a field and analyzed in the laboratory.

Viral RNAs are detectable in plant and insect preparations using fluorescently labeled (usually by Cy3 or Cy5) synthetic primers complementary to the RNAs. The samples are observed with a fluorescence microscope or a laser confocal microscope.

A microarray containing 279 40-mer oligonucleotide probes was constructed to detect ten important tomato viruses. It included sequences derived from TYLCV CP DNA. It allowed detecting TYLCV but was unable to discriminate between TYLCV and TYLCVSV.

Nucleic acid amplification

PCR is widely used for the diagnosis of TYLCV strains. The virus is detectable in very small amounts of infected plant and vectors. Subsequently, the amplicon can be sequenced to identify the TYLCV strain.

Whitefly GroEL, whether extracted from *B. tabaci* or overexpressed in *E. coli*, binds begomoviruses with strong affinity. This property was exploited to trap TYLCV by incubating infected plant and viruliferous whitefly extracts with GroEL-coated PCR tubes. TYLCV was then detected by PCR.

RCA allows amplifying full-length viral genomes, including TYLCVs, in a single-step and without the use of specific primers. The amplicons can be sequenced for identification and phylogenetic analyses. RCA was implemented to generate infectious genomic clones directly from plant and whitefly DNA, and from specimens sometimes stored for decades, including TYLCV.

Sequencing

Mass sequencing (millions of 100–700 nt reads) using platforms such as Illumina combined with bioinformatic softwares was used to study the effects of TYLCV on the transcriptome, and on virus-related RNAi and microRNA populations of plants and whiteflies.

Metagenomic analyses of whiteflies and infected plants allowed delivering fast and inexpensive information on the presence of TYLCV isolates and other viruses (some previously unknown). This is an exquisite tool to survey the diversity and movement of TYLCV in small as well as large environmental settings.

Treatment

Prevention

Planting in whitefly-free period, eradication of inoculum

Disease management strategies include the elimination of possible inoculum (residual infected plants and weeds), and planting when whitefly population pressure is low. In all regions where TYLCV is endemic, seedlings to be planted in the field or greenhouse need to be grown under cover to prevent early infection.

Cultures under cover

Growing tomato in net or plastic houses covered with insect-proof 50-mesh screens and with double-doors, constitutes the optimal solution for crop protection against the TYLCV whitefly vector. Sticky yellow polyethylene sheets are used to decrease the pressure of the whitefly population in greenhouses, with limited success. Ultraviolet (UV)-absorbing plastic sheets or UV-absorbing 50-mesh screens used as nethouse covers, greatly repel whiteflies and reduce TYLCV incidence.

Chemical control of whiteflies

TYLCV is usually controlled by spraying insecticides. Many chemicals used in the past, such as organophosphates, carbamates and pyrethroids, effectively reduced whitefly population, until the insects developed resistance. More potent insecticides, with novel modes of action, such as imidacloprid, have been introduced in the 1990s. As anticipated, whitefly populations resistant to imidacloprid have emerged in many places.

Biological control of whiteflies

Whitefly IPM control in greenhouse tomato production of Europe, and to a lesser extent of the USA, includes biological control with natural enemies such as the parasitic wasp *Eretmocerus* spp. and the predatory bug *Nesidiocorus tenuis*, used alone or in combination. These practices are not yet common in the open-field cropping systems.

Breeding for Resistance

Certain accessions of the wild tomato species *S. chesmanii*, *S. chilense*, *S. habrochaites*, *S. peruvianum*, and *S. pimpinellifolium* are resistant/tolerant to whitefly-mediated inoculation (show mild or no symptoms, but contain virus). Breeding programs aimed at producing tomato cultivars resistant to TYLCV started in the late 1960s. They were based on the introgression of resistance from wild tomato species into the domesticated tomato *Solanum esculentum*.

The discovery of loci, and later on of genes, associated with TYLCV resistance, was facilitated by the development of saturated maps based on DNA polymorphism distinguishing resistance from susceptibility (RFLP, AFLP, SSR, SCAR, etc.). Altogether six loci, coined *Ty-1* to *Ty-6*, were found to be associated with TYLCV resistance. The *Ty-1* locus originating from *S. chilense* was mapped to tomato chromosome 6. Ultimately, *Ty-1* was identified as coding for an RNA-dependent RNA polymerase. Another TYLCV resistance locus, *Ty-3*, was shown to be allelic to *Ty-1*. *Ty-2* was introgressed from *S. habrochaites* and was located on chromosome 11. *Ty-2* encodes a nucleotide-binding domain and leucine-rich repeat-containing (NB-LRR) gene. *Ty-4* was introgressed from *S. chilense* and mapped to chromosome 3. *Ty-5* was introgressed from *S. peruvianum* and mapped on chromosome 4. *Ty-5* encodes a messenger RNA surveillance factor Pelota, which is involved in ribosome recycling phase of protein synthesis. *Ty-6* originated from *S. chilense* and was located on chromosome 10. Combination of resistance loci from different sources in a single tomato line often enhances resistance.

Today, most commercial tomato varieties are resistant/tolerant to TYLCV; in most cases, they have incorporated *Ty-1*. They remain symptomless (or with mild symptoms) upon infection, and yield nearly as uninfected plants (Fig. 3). However, *Ty-1*-mediated resistance collapses under high disease pressure. It was recently reported in Jordan and in Israel that a newly found betasatellite associated with TYLCV overcomes the resistance based on *Ty-1*.

Genetic Engineering

Expression of viral genes

A variety of strategies have been devised based on the pathogen-derived resistance concept, which involves the expression of functional as well as dysfunctional viral genes. A transgenic interspecific F1 hybrid *S. lycopersicum* x *S. pennellii* expressing the TYLCV CP under the Cauliflower mosaic virus (CaMV) 35S promoter showed delay and remission of symptoms upon whitefly-mediated inoculation.

Fig. 3 TYLCV-infected tomato fields planted with susceptible and resistant tomato genotypes. Note that the susceptible plants are stunted; they will not produce fruits. For comparison, the resistant plants will remain symptomless, or with mild symptoms and will yield.

Tomato and tobacco plants transformed with a truncated (2/5) TYLCV *Rep* gene under the control of the 35S CaMV promoter. Following whitefly-mediated inoculation with TYLCV in the laboratory, T2 generation lines evaluated in the field in Florida showed variable rates of resistance. However, the TYLCV-resistant plants were susceptible to the bipartite begomovirus Tomato mottle virus (ToMoV) from Florida. Similarly, tomato plants transformed with the *Rep* gene of TYLCSV truncated in its 3' end exhibited resistance to TYLCSV but were susceptible to the related strain from Spain.

Expression of antisense sequence of the TYLCSV *Rep* gene in transgenic *Nicotiana benthamiana* resulted in lesser virus replication. The incorporation of a ribozyme structure into the antisense construct did not increase the efficiency of the system.

RNAi

The silencing-based RNA interference (RNAi) antiviral defense mechanism was exploited to express siRNA directed against TYLCV genes. Post-translational gene silencing (PTGS) was activated through the transgenic expression of hairpin dsRNA cognate to the target viral genome. PTGS was efficient but was highly-sequence dependent.

In the early experiments, non-coding conserved regions from the genome of TYLCV, TYLCV-Mild, and several TYLCSVs from Spain, were used to design constructs aimed at triggering broad resistance against different strains of TYLCV. Upon whitefly-mediated inoculation, a high level of resistance was obtained against all three viruses, which correlated with the accumulation of TYLCV-specific siRNAs, indicating that PTGS can be used to engineer geminivirus-resistant plants.

A hairpin RNAi (hpRNAi) aimed at expressing dsRNA homologous to sequences of the IR, the CP, V2 and *Rep* genes of TYLCV from Oman was used to transform tomato plants. Nine transgenic lines were obtained, which showed various levels of resistance upon TYLCV agroinoculation.

RNAi directed at TYLCV *Rep* gene was expressed in transgenic tomato plants. The homozygous F4 and F6 generations exhibited resistance to TYLCV in the greenhouse and in whitefly-infested fields, and contained high amounts of small RNAs.

CRISPR/Cas9

The clustered regularly interspaced short palindromic repeats system (CRISPR/Cas), which protects prokaryotes from potentially deleterious foreign DNA, was used to engineer the genome of tomato and *N. benthamiana* to confer immunity to TYLCV. Targeting the TYLCV CP and *Rep* sequences with Cas9-single guide RNA resulted in efficient virus interference. The treated plants had low TYLCV load and their T3 progeny was tolerant to TYLCV. Therefore, genome editing might be the tool of the future to obtain TYLCV-resistant tomato genotypes.

TYLCV Transmission to Tomato and Host Response

Transmission by whiteflies

In nature, TYLCV is transmitted by the whitefly *B. tabaci* in a persistent circulative manner. Transmission of TYLCV to tomato by *B. tabaci* B biotype has been studied thoroughly. The virus is transmitted to tomato plants after vector feeding on infected tomato plants or alternative hosts. The incidence of the disease is directly correlated with the pressure of the whitefly population. One to three viruliferous insect are able to infect a tomato plant. The efficient AAP is 15–30 min, the latent period is 8–24 h, and the efficient inoculation access period (IAP) is at least 15 min. Female *B. tabaci* are better vectors than males. The ability of the whiteflies to transmit TYLCV to tomato test plants decreases with age, from 100% to 10%–20% during their 4–5-week adult lifetime.

Response of plants to TYLCV infection

RNAi

RNAi is a natural defense mechanism against viruses. It is triggered by the processing of virus-derived dsRNA by host Dicer-like (DCL) enzymes into 21–24 nt small interfering RNA (siRNAs). Viral siRNAs bind Argonaute (AGO) proteins and guide the resulting RNA-induced silencing complexes toward their cognate RNA molecules, leading to post-transcriptional or transcriptional silencing in the case of RNA and DNA viruses, respectively. Viral siRNAs can move to other cells and into the phloem. As a counter-defense, geminiviruses encode one or more silencing suppressor proteins. TYLCV C2 and V2 proteins were reported to suppress RNA silencing by inhibiting the siRNA amplification stage. Infection depends on the balance between silencing and suppression. This balance can be shifted to virus tolerance by overexpressing antiviral dsRNA in the form of RNA hairpins in transgenic plants.

Aggregates

Upon tomato infection, TYLCV CP-DNA complexes accumulate in the phloem associated cells of tomato leaves. At the early stages of infection, punctate aggregates are detected in the cytoplasm; in the later stages aggregates of increasing size are localized in cytoplasm and nuclei. Nuclear aggregates contained infectious particles transmissible to test plants by whiteflies. The formation of large aggregates was delayed in TYLCV-resistant tomatoes, perhaps as part of the resistance mechanism.

Transcriptome and metabolome

TYLCV induces significant changes already during the first days after inoculation, changes that exacerbate as infection progresses. They include the activation of genes involved in general stress-response, hormone biosynthesis, signal transduction, RNA regulation and processing, induction of the ubiquitination pathway, and initiation of autophagy. Photosynthesis decline, is accompanied by release of hexose that activates defense response or, if failing, promote pathogen replication and disease expression.

Upon TYLCV infections, tomato plants emit reactive oxygen species (ROS), pathogenesis-related (PR), and wound-induced proteins. Sources of carbon and nitrogen are highly affected, accompanied by changes in the abundance of various classes of metabolites such as amino acids and polyamines, phenolic and indolic metabolites. Hence, upon TYLCV infection, there is a coordinated reprogramming of phenylpropanoid, tryptophan/nicotinate, urea/polyamine, and salicylic acid biosynthesis pathways leading to the production of defense compounds.

Involvement of heat shock and quality control proteins in the establishment of TYLCV infection

TYLCV does not induce a hypersensitive response and cell death upon whitefly-mediated infection of susceptible tomato plants. Cell death can be induced by the inactivation of heat shock protein 90 (HSP90) as well as by silencing the genes *Hsp90* and *Sgt1* (HSP90 co-chaperone), causing the dissociation of the 26S proteasome and a decrease of its peptidase activity, which led to the accumulation of damaged ubiquitinated proteins. TYLCV alleviates cell death and these accompanying effects to create an environment suitable to its replication.

The interactions between TYLCV and HSP70 and HSP90 chaperons in plants and vectors are essential for virus infection to proceed. In infected host cells, HSP70 and HSP90 are redistributed from a soluble to an aggregated state. These aggregates contain, together with viral DNA/proteins and virions, HSPs and components of the protein quality control system such as ubiquitin, 26S proteasome subunits, and the autophagy protein ATG8. TYLCV CP can form complexes with HSPs in tomato and whitefly. Nonetheless, HSP70 and HSP90 play different roles in the viral cell cycle in the plant host. In the infected host cell, HSP70, but not HSP90, participates in the translocation of CP from the cytoplasm into the nucleus. Viral amounts decrease when HSP70 is inhibited, but increase when HSP90 is downregulated. In the whitefly vector, HSP70 impairs the circulative transmission of TYLCV; its inhibition increases transmission.

Glossary

Frameshifting A ribosome shifting its reading frame during protein translation.

Higher-order RNA structures RNA secondary and tertiary structures, such stem-loops or pseudoknots, respectively.

Monocot A class of angiosperm plant with a single embryonic leaf and parallel veins.

Nanoparticle A microscopic particle in the approximate range of 1–100 nm.

Open reading frame A segment of RNA encoding a protein.

T Triangulation number, which describes the icosahedral geometry of spherical viruses.

Tombusvirid A member of the virus family *Tombusviridae*.

Transcription Herein, describes the process by which viral sg mRNAs are synthesized.

Type A designated member that represents a group.

Introduction

Tombusvirus is the type genus in the family *Tombusviridae*, which currently includes a total of sixteen genera. The members of this extensive family possess linear, single-stranded, positive-sense RNA genomes that are packaged into spherical particles and, collectively, infect a wide variety of plant hosts. The overall grouping of these viruses is based on the presence of a conserved RNA-dependent RNA polymerase (RdRp). Within the family, members are further subdivided into subfamilies, genera, and species based on similarities in gene expression strategies and encoded proteins. In this article, the genus *Tombusvirus* and those genera that are most closely related to this genus, *i.e.*, *Aureusvirus* and *Zeavirus*, are described.

Taxonomy, Phylogeny, and Evolution

The family *Tombusviridae* resides within the realm *Riboviria*, and includes three subfamilies (*Procedovirinae*, *Regressovirinae* and *Calvusvirinae*) and sixteen genera (*Alphacarmovirus*, *Alphanecrovirus*, *Aureusvirus*, *Avenavirus*, *Betacarmovirus*, *Betanecrovirus*, *Dianthovirus*, *Gallantivirus*, *Gammacarmovirus*, *Macanavirus*, *Machlomovirus*, *Panicovirus*, *Pelarspovirus*, *Tombusvirus*, *Umbravirus*, and *Zeavirus*), each of which contain member species that range in number from one to seventeen. Most genera belong to the subfamily *Procedovirinae*, all of which express their RdRps via translational readthrough of a stop codon. In contrast, dianthoviruses are in *Regressovirinae*, because they translate their RdRps via frameshifting. Umbraviruses, which do not encode a capsid gene, occupy *Calvusvirinae*. The current taxonomy is the result of recent reorganization within the family, and additional modifications and refinements are anticipated in the near future. Consequently, updates should be monitored by visiting the International Committee on Taxonomy of Viruses website (see "Relevant Websites section").

Taxonomic classification of tombusvirids is based primarily on the structural relationship of their viral RdRps. All contain supergroup-II RdRps that share high levels of amino acid sequence identity, including several tombusvirid-specific motifs located in C-terminal regions. Indeed, taxonomic organization down to the level of species can be guided entirely by sequence comparisons of RdRps. Nonetheless, additional features distinct to specific genera, such as the type of movement protein or silencing suppressor encoded, also aid in appropriate grouping. The notable level of diversity observed within these two protein types suggests that they were acquired via recombination-mediated modular transfer of gene cassettes.

Phylogenetic analysis of the RdRps of tombusvirids have revealed an evolutionary tree that is comprised of distinct lineages (Fig. 1). The largest two of these lineages can be defined roughly as either tombusvirus-like or carmovirus-like, with the latter further classified into numerous genera. Only four genera reside within the tombusvirus-like clade, *Tombusvirus*, *Aureusvirus*, *Zeavirus* and *Betanecrovirus*. However, the latter genus has movement and capsid proteins typical of carmoviruses. Consequently, betanecroviruses are not discussed here, and instead are presented in the article covering necrovirus-like viruses. Of the remaining three tombusvirus-like genera, all share high degrees of similarity with respect to gene order, protein relatedness, and expression strategies. Based on RdRp phylogenetic analysis, zeaviruses are predicted to be more closely related to tombusviruses than aureusviruses. However, the zeavirus host range of monocot plants (*e.g.*, grasses) is more akin to certain aureusviruses. Thus, although these genera are closely related, they also possess features that distinguish them from one another. Currently, the genus

Fig. 1 Phylogenetic tree depicting evolutionary relationships of genera in the family *Tombusviridae* based on the RdRp amino acid sequences of tombusvirids. The tombusvirus-like lineage is shaded in yellow and the genera discussed in this article are shown in red. Adapted from Gunawardene, C.D., Donaldson, L.W., White, K.A., 2017. Tombusvirus polymerase: Structure and function. *Virus Research* 234, 74–86.

Tombusvirus is composed of seventeen species, including *Tomato bushy stunt virus* (TBSV), which is the type virus of both the genus and family (Table 1). The less crowded *Aureusvirus* genus has five confirmed member, with *Pothos latent virus* (PoLV) designated as the type species. Presently, the genus *Zeavirus* contains only one member, its type species, *Maize necrotic streak virus* (MNeSV).

Virion Structure, Assembly, and Disassembly

Members of the tombusvirus-like group form non-enveloped, spherical virions that encase a single viral RNA genome. The capsids are ~30 nm in diameter, have T=3 icosahedral symmetry, and are composed of 180 subunits of a capsid protein (Fig. 2). The capsid proteins of tombus- and aureusviruses are of similar molecular masses, 40 and 41 kDa, respectively. In contrast, that for zeaviruses is substantially smaller, 27 kDa, due to the absence of a C-terminal domain present in the other two capsid proteins.

Among the three tombusvirus-like genera, the particles of tombusviruses have been studied most extensively. Going from N- to C-terminus, these capsids are composed of three distinct structural domains, RNA-binding (R), shell (S), and protruding (P). Orientation of the subunits within a capsid is such that C-terminal P-domains extend out from the particle surface formed by the S-domain, while the N-terminal R-domain, a highly basic region, is positioned internally and neutralizes the negatively charged phosphate groups in the packaged RNA genome. The single capsid subunit is able to assume three different conformations that allow for its packing into the 5- and 3-fold centers of particle symmetry. Only conformation A subunits reside at the 5-fold axes (blue), while alternating B and C subunits (red and green, respectively) fill the 3-fold centers (Fig. 2). The P-domains of two adjacent subunits interact in AB or CC dimers to form ninety projections that can be observed in electron micrographs. This latter feature is not present in zeaviruses, as their capsid proteins lack the C-terminal P-domain that forms these protrusions.

Details of the process of virion assembly in these viruses remain largely unknown. For many viruses, key regions of their RNA genomes have been identified as packaging signals that bind to capsid subunits and initiate virion assembly. Currently, no corresponding RNA assembly signals in the genomes of tombusvirus-like viruses have been identified. However, studies on the capsid protein of the tombusvirus Cucumber necrosis virus (CuNV) have identified a determinant in the R-domain, a basic KGKKGK motif, that dictates the efficiency of capsid assembly, as well as particle size, i.e., T=1 (60 subunits) versus T=3 (180 subunits). Furthermore, a second basic

motif in the arm region connecting the R- and S-domains is important for determining the amount of full-length RNA that gets incorporated into virions and may contribute to the specificity of packaging viral genomes. Accordingly, interactions involving these positively-charged interior regions of the capsid and the negatively-charged viral RNA are proposed to mediate virion formation; the detail of which remain to be determined.

An equally important aspect of virion function is its ability to disassemble and release its viral genome in newly infected cells. Studies with the tombusvirus CuNV suggest that plant Hsp70 protein chaperone homologs, Hsc70 or Hsc70-2, assist in CuNV disassembly. Hsc70-2 copurifies with CuNV particles, overexpression of Hsc70 in plants facilitates infections, and incubation of Hsc70 with particles destabilizes them. These observations are consistent with the involvement of Hsc70 or its homologs in

Fig. 3 Cartoon representation of the plus-strand RNA genomes of the type species for tombusvirus-like genera: *Tomato bushy stunt virus* (TBSV), *Pothos latent virus* (PoLV) and *Maize necrotic streak virus* (MNeSV). Encoded proteins are represented by color-coded boxes along with the molecular masses of corresponding proteins (p), in kDa. The functions of proteins are labeled for the TBSV genome, with corresponding proteins in the other two genomes having equivalent functions. RT indicates the position of the stop codon for accessory replication proteins in the genomes where translation readthrough occurs to produce their RNA-dependent RNA polymerases (RdRps).

mediating disassembly of this tombusvirus. Moreover, since Hsp70 homologs also associate with virions of the aureusvirus *Cucumber leafspot virus*, and overexpression of Hsc70-2 in host plants mediates more robust infections, this proposed mode for unpacking may also apply to this related genus.

Genome Structure

The linear, plus-sense, single-stranded RNA genomes of tombusvirus-like viruses are neither 5'-capped nor 3'-polyadenylated. The sizes of these genomes are ~4.1, ~4.2, and ~4.8 kb in length, respectively, for ze-, aureus-, and tombusviruses (**Fig. 3**). These genomes encode five proteins, and share a similar gene composition and organization that is unique among tombusvirids. Encoded 5'-proximally is an auxiliary RNA replication protein, homologs of which are present at comparable genomic positions in all members of the family. Translational readthrough of the stop codon of this protein leads to the production of a supergroup-II RdRp, also a common product in all tombusvirids. Encoded downstream from the polymerase is a single capsid protein, which contains a P-domain in tombus- and aureusviruses that is absent in zeaviruses. The feature that clearly distinguishes the tombusvirus-like group from other genera is their movement and suppressor of gene silencing proteins. These two proteins are encoded as overlapping open reading frames (ORFs) and are positioned 3'-proximally in viral genomes (**Fig. 3**). The coding regions of the suppressor proteins are smaller than, and are located entirely within, corresponding movement protein ORFs. However, because the two ORFs reside in different reading frames, each encodes a structurally unique protein. Homologs of these two viral products are not found in other tombusvirids, thereby defining these genera as a distinctly-related trio.

In addition to their role in encoding viral proteins, these plus-strand RNA genomes also house multiple RNA elements that are involved in regulating different viral processes. Some of these elements are local, such as the promoter sequences located at the 3'-termini of these genomes. Interestingly, tombusviruses also utilize at least six different sets of intragenomic, long-range, base pairing RNA-RNA interactions for different viral functions. Some of these span almost the entire length of these 4.8 kb genomes, whereas others traverse shorter distances, while still exceeding a kilobase in length. The presence of these interactive RNA-RNA networks suggests that there must be a significant level of structural organization in these viral genomes to assist bringing distal partner regions together and to coordinate the different interactions and their corresponding functions. Indeed, analysis of the RNA secondary structure of the complete TBSV genome revealed that much of it is ordered and forms discrete RNA domains (**Fig. 4**). Notably, the predicted structure included only two of the six long-range interactions needed during viral infections (*i.e.*, AS1-RS1 and DE-CE) (**Fig. 4**). This suggests that dynamic reorganization of the genome is required to achieve the six different long-range interactions (**Fig. 5(A)**). Such structural rearrangements could be facilitated by viral or host factors that are able to direct particular RNA folding pathways. In this regard, the auxiliary RNA replication protein p33 of TBSV has been found to possess RNA chaperone activities, and thus could participate in such genome reorganizing events.

Gene Function

Studies exploring protein function in the group have been carried out largely in tombusviruses (*e.g.*, TBSV), however the corresponding proteins in the other two genera are predicted to operate similarly. Both of the 5'-proximally encoded proteins in these viral genomes are essential for viral RNA synthesis. The auxiliary RNA replication protein of TBSV, p33, is a multifunctional master regulator of viral RNA replication that interacts with a myriad of host factors. This protein is also a major structural component of virus replication complexes (VRCs), the sites of viral RNA synthesis. VRCs also contain an RdRp, p92 for TBSV, that catalyzes both replication of the genome and transcription of viral subgenomic (sg) mRNAs. Additional information on these two processes are provided in subsequent sections.

Fig. 4 RNA secondary structure model of the TBSV genome. RNA domains within the genome are labeled and color-coded according to their relative sizes: large (green), medium (red) or small (blue). Inter-domain regions are depicted in black. The RNA segments that participate in known functional long-range RNA–RNA interactions are labeled (refer to Fig. 5 for details). Only the AS1–RS1 and DE–CE interactions involved in sg mRNA transcription are base paired in this genome structure. Adapted from Wu, B., Grigull, J., Ore, M.O., Morin, S., White, K.A., 2013. Global organization of a positive-strand RNA virus genome. *PLoS Pathogens* 9 (5), e1003363.

Fig. 5 TBSV RNA genome and sg mRNAs. (A) TBSV genomic RNA, with encoded proteins represented by boxes. Proteins translated directly from the genome, p33 and p92, are represented by grey bars and sg mRNA transcription start sites within the genome are labeled sg1 and sg2. Long-range RNA–RNA interactions involved in different viral processes are indicated by double-headed arrows above the genome and are color coded: 5'UTR–3'CITE, translation initiation; PRTE–DRTE, ribosome readthrough; UL–DL, genome replication; AS1–RS1, sg mRNA1 transcription; AS2–RS2, sg mRNA2 transcription. DE–CE is a second long-range interaction needed for sg mRNA2 transcription. (B) TBSV sg mRNAs. The two sg mRNAs transcribed during infections are shown along with the proteins that are translated from them.

Movement proteins are necessary for cell-to-cell movement of viral infections in plants. The local spread of an infection occurs through plasmodesmata, which are channels that connect adjacent plant cells. This process requires the assistance of a virally-encoded movement protein that facilitates transport of viral RNA to, and through, these intercellular junctions. This event requires modification of the structure of plasmodesmata to allow transit and, in tombusviruses, this action is mediated by p22. Properties of p22, such as binding to RNA and localization to cell membranes and walls, are consistent with this role. The viral genome is likely transported intra- and intercellularly as a p22-RNA complex, and may be shuttled by host factor HFi22, a homeodomain-containing protein, that interacts with p22. This concept is supported by the observation that some movement-deficient p22 mutants are no longer able to interact with HFi22.

Gene silencing is an antiviral mechanism utilized by plants. The first step in this defence mechanism occurs when long double-stranded (ds) viral RNAs generated during genome replication are bound and cleaved by the host protein dicer into small dsRNAs, termed small interfering RNAs (siRNA). Subsequently, single-strands of these siRNAs are loaded into a RNA-induced silencing complex (RISC) that uses them as guides to base pair with and cleave viral genomes. To counteract this attack, plant viruses encode suppressors of gene silencing that are able to inhibit different steps in the process. The p19 suppressor of tombusviruses functions as a homodimer that binds size-specifically to siRNAs generated by dicer. In doing so, it prevents them from being loaded into RISC, thereby preventing virus genome-specific RNA targeting and cleavage by this complex. The smaller p14 homologue in aureusvirus functions in a similar manner but, due to its lack of size-specificity, it also binds to longer dsRNAs.

Gene Expression

Gene expression in these viruses involves cap-independent translation, ribosome readthrough, sg mRNA transcription, and leaky scanning. Intriguingly, for function, all but the latter activity require RNA-RNA interactions that span large distances within the viral genomes (**Fig. 5(A)**). All tombusvirid RNA genomes lack a 5'-cap and a 3'-poly(A) tail. Instead, they contain one of several types of 3'-cap independent translational enhancer (3'-CITE) in their 3'-untranslated regions (3'-UTRs). 3'-CITEs in the tombusvirus-like group are higher-order RNA structures that bind to translation initiation factor 4F (eIF4F). These 3'-CITEs, while bound to eIF4F, also interact with the 5'-UTRs of their genomes, via a long-range RNA-RNA base pairing interactions (**Fig. 5(A)**). This positions the bound eIF4F near the 5'-end of the genomes, allowing for 43S subunit recruitment that mediates translation of the auxiliary replication proteins, p33 in the case of TBSV (and the p92 RdRp via readthrough). Though closely related, the three genera contain different types of 3'-CITEs; tombusviruses have Y-shaped versions (except for, Cucumber Bulgarian latent virus, CBLV, which has an I-shaped type), aureusviruses contain either a PTE or I-shaped class, while zeaviruses contain only I-shaped versions. Accordingly, modularity in these viral genomes also exists with respect to translational regulatory RNA elements.

Viral RdRps, such as p92 in TBSV, are expressed by translational readthrough of the stop codon for the auxiliary replication protein. Programmed ribosome readthrough occurs when RNA elements in a message promote the use of near-cognate tRNAs for decoding of a termination codon. In tombusviruses, this process requires an extended stem-loop RNA structure, termed RTSL, positioned just 3' to the stop codon. However, in order for readthrough to occur, a sequence in RTSL (termed PRTE) must base pair, via a long-range RNA-RNA interaction, with a segment in the 3'-UTR of the genome (DRTE) (**Fig. 5(A)**). This interaction shuts down minus-strand RNA synthesis during readthrough, thereby preventing a conflict between these processes that occur in opposite directions on the viral genome. Similar local and long-distance RNA structural requirements for readthrough production of RdRp are also predicted for aureusviruses and zeaviruses.

Within the context of tombusvirus-like genomes, the three ORFs encoded in their latter halves are translationally silent. Consequently, expression of these gene products requires the transcription of viral sg mRNAs. During infections, two sg mRNAs are synthesized that encode at their 5'-ends either the capsid protein ORF or the two overlapping ORFs. The capsid protein is translated from the larger sg mRNA1, while both the movement and silencing suppressor are translated from sg mRNA2 (**Fig. 5(B)**). The latter protein is translated when 43S subunits scan past the more 5'-proximally positioned movement protein start codon and initiate at the downstream suppressor protein start codon, a mechanism referred to as leaky scanning.

Transcription of sg mRNAs involves premature termination of the RdRp while synthesizing complementary genomic minus-strands. RdRp termination occurs when the viral polymerase encounters certain higher-order RNA structures in a genome, called attenuation structures. This results in truncated minus-strands that include transcription initiation sites, for either sg mRNA1 or 2, at their 3'-ends. These sg mRNA-sized minus-strands are then used as templates to transcribe the two different size classes of sg mRNAs. Interestingly, in tombusviruses and zeaviruses, the attenuation RNA structures for both sg mRNA1 and 2 are formed by long-range, base pairing, RNA-RNA interactions (AS1-RS1 and AS2-RS2, respectively) (**Fig. 5(A)**). These genome-level interactions may provide an RNA-based mechanism to coordinate transcription with other viral processes. Aureusviruses have comparable long-distance AS2-RS2 interactions for sg mRNA2 production, but, for sg mRNA1, the attenuation structure is formed by a locally-folded section of RNA. Although variations in attenuation structures exist, the sg mRNAs generated are structurally similar in that all are 3'-coterminal with their cognate genomes. This feature ensures that these smaller viral messages contain 3'-CITEs, which enhance their translation via cognate 5'UTR-3'CITE interactions.

Genome Replication

Tombusvirus genome replication has been investigated extensively in different systems, including in vitro cell extracts, plant protoplasts, whole plants, and surrogate yeast cells. These studies, particularly those carried out in yeast-based systems, have

Fig. 6 Steps in VRC assembly and RNA synthesis in TBSV. (A) Peroxisome membrane targeting, (B) VRC assembly and (C) Viral RNA synthesis. Plus- and minus-strand genomes are represented as a solid and dotted lines, respectively. RdRps are shown at different steps in viral genome replication in (i) through (iv). See key for the identity of molecular components and refer to text for details. Diagram is not to scale. Adapted from Gunawardene, C.D., Donaldson, L.W., White, K.A., 2017. Tombusvirus polymerase: Structure and function. *Virus Research* 234, 74–86.

generated a large body of information that has allowed for the development of detailed models for various steps in this process. In general, the overall progression during infections can be roughly divided into three phases (1) membrane targeting, (2) VRC assembly, and (3) viral RNA synthesis. Here, these fundamental steps are summarized along with descriptions of the key viral and cellular factors involved, using TBSV as the example (Fig. 6).

At the centre of this process are the viral proteins p33 and p92, with the former being responsible for orchestrating the majority of events required for productive RNA genome replication. p33 is a membrane-anchored protein that possesses multiple domains and motifs that allow it to interact with diverse host factors that are required at different steps in the process. Also important for p33's activity is its ability to multimerize and interact with p92, and an early stage in RNA replication involves the targeting of these two viral proteins to specific intracellular membranes which, for TBSV, are peroxisomal (Fig. 6(A)). Membrane localization is dependent on N-proximal targeting sequences present in both of these proteins as well as interaction with peroxisomal biogenesis factor 19 (pex19). The viral genome also has to be shuttled to this membrane location, and this is accomplished by p92/p33 binding to an RNA structure, RII, located in the p92 coding region (Fig. 6(A)).

Assembly of VRCs rely heavily upon p33 activity. VRCs are invaginations of intracellular membranes that maintain a narrow neck with the cytosol. p33 multimers are a key structural component of these so-called spherules, and their internal compartments house the

RdRp and other factors necessary for viral RNA synthesis (Fig. 6(B)). A key step in forming these curved compartments is the hijacking of the host endosomal sorting complexes required for transport (ESCRT). p33 redirects the ESCRT system to form VRCs by interacting with different key components, such as Vps23p. The nature of the lipids within VRC membranes is also important for function. Phosphatidylethanolamine and phosphatidylcholine have stimulatory effects on VRC activity (Fig. 6(B)). To this end, p33 upregulates phospholipid production by interacting with and modulating regulatory proteins Opi1p and Scs2p. Other membrane components, such as sterols, which decrease membrane fluidity and directly bind to p33, also increase VRC function. Here again, p33 is involved in seizing control of these molecules by binding to and modifying the activity of oxysterol-binding proteins (ORPs), which are involved in controlling sterol distribution between closely associated membranes. Actin filaments also contribute to this process by stabilizing membrane contact sites, which allows for exchange of sterols from the endoplasmic reticulum (ER) to peroxisomal membranes that are destined for VRC formation. Stable actin filaments are required for this to occur, and an inhibitory interaction of p33 with cofilin, an actin depolymerization factor, ensures that a polymerized state is maintained. ER-peroxisomal intermembrane junctions thus represent critical cellular hubs for preparing appropriately composed lipid bilayers for VRC assembly.

The p92 RdRp inside assembled VRCs synthesizes a full-length complementary negative-strand of a genome that is then used repeatedly as a template to produce multiple copies of progeny genomes (Fig. 6(C)). However, prior to any RNA synthesis, p92, in association with a phospholipid-enriched membrane, has to be activated by cellular protein chaperone Hsp70. Other host proteins are also needed during genome replication. Two translation elongation factors, eEF1A and eEF1B γ , are involved in the early stages of minus-strand synthesis (Fig. 6(C)(i)). Both bind to a promoter region in 3'-end of the genome and facilitate RdRp positioning and promoter access, respectively. Additionally, p92 that is bound to the RII RNA structure in RdRp-coding region of the viral genome is repositioned to the 3'-end by a long-range RNA-RNA interaction, UL-DL (Fig. 5(A)). p92 initiates RNA synthesis at a promoter sequence located at the 3'-end of the viral genome (Fig. 6(C)(ii)). Upon completion of minus-strand genome synthesis, the RNA helicase RH20 mediates release of p92 from the dsRNA intermediate, and facilitates its rebinding to the minus-strand template. This latter step is also assisted by two other RNA helicases, RH2 and RH5, as well as glyceraldehyde 3-phosphate dehydrogenase (GAPDH), all of which interact with the minus-strand (Fig. 6(C)(iii)). Notably, the activities of these helicases, as well as Hsp70, require ATP. This requirement is met by the recruitment of glycolytic enzymes, namely ATP-generating phosphoglycerate kinase and pyruvate kinase, to the vicinity of VRCs. The resulting activities of these enzymes leads to high local levels of ATP for components of the VRCs, thereby allowing for robust virus genome replication. Newly synthesized progeny viral genomes leave VRCs and enter the cytosol via the neck of spherules (Fig. 6(C)(iv) and (v)).

Subviral RNAs

Tombusviruses are known to associate with two distinct types of subviral RNAs, satellite RNAs (satRNAs) and defective interfering RNAs (DI-RNAs). SatRNAs are naturally-occurring, noncoding, small linear RNAs that require coinfection with a standard virus, termed helper virus, for their replication and packaging. They are also dependent on their helper virus for gene silencing suppression and movement functions. Structurally, satRNAs do not share sequence identity with their helper virus. The discrete sequence of these RNAs is a paradoxical feature, because they utilize the same RdRp and capsid protein as their helpers. This suggests that they may engage viral and host factors in unique ways. SatRNAs have been found only in tombusvirus infections. Four distinct satRNAs have been identified, with the first being satRNA-Cym, which was discovered in association with Cymbidium ringspot virus (CymRSV). Subsequently, three others were identified in different TBSV infections, satRNA-B1, B10, and L. These satRNAs have lengths in the range of 600–800 nt and maintain 5'-ends that form higher-order RNA structures similar to those found in the 5'-UTRs of their helper genomes. When present in infections, satRNAs can increase, decrease, or have no effect on symptoms. Of the four tombusvirus satRNAs, only satRNA-B10 modulates infections; *i.e.*, it attenuates symptoms and prevents death of infected plants.

The other class of subviral RNA associated with tombusvirus infections are DI-RNAs. Similar to satRNAs, DI-RNAs are small, parasitic, noncoding, linear RNAs that depend on their helper virus for replication and packaging. However, unlike satRNAs, DI-RNAs are not normally found in natural infections, and they contain sequences that correspond directly to those in their helper virus genomes. DI-RNAs associated with tombusviruses were the first to be discovered for any plant virus. These 400–600 nt long RNAs contain sort genomic segments from both termini and two different internal regions (RI through RIV), and these segments are either essential (RI, RII and RIV) or greatly enhance (RII) replication of the DI RNA. This knowledge of DI-RNA structure and function also aided the identification of corresponding RNA replication elements in full-length viral genomes. Moreover, due to their small size, efficient accumulation in coinfections, and absence of coding functions, DI-RNAs have been excellent tools for studying virus RNA replication; particularly in the yeast-based system. They have also provided insights into viral RNA recombination, a process mediated by template hopping or switching by the viral RdRp during RNA synthesis. DI-RNA formation, via recombination, and their subsequent accumulation is promoted when infections are passaged at high virus titer; an artificial condition that favors coinfection of cells with helper genomes and nascently generated DI-RNAs. Although they are not found in infections in the wild, adding DI-RNAs to tombusvirus infections in laboratory experiments revealed their ability to suppress helper virus levels and the symptoms induced in plant hosts. This interference was initially believed to be due primarily to competition with the helper virus for RNA replication factors. However, tombusvirus DI-RNAs have also been shown to strongly activate gene silencing in coinfections, while being highly resistant to its effects. Thus, the disease attenuation observed could be caused by enhanced targeting and degradation of the helper genome.

A third class of subviral RNA, a satellite virus (SV), is present in some infections of the aureusvirus *Maize white line mosaic virus* (MWLMV). SV have properties similar to those of satRNAs, except that they encode their own unique capsid protein, in which their RNA is packaged. The linear RNA genome of SV-MWLMV is ~1.2 kb in length and encodes a 24 kDa capsid protein. Together, these components form spherical virions of ~17 nm in diameter, which are about half the size of the ~35 nm virions of the helper MWLMV. These particle sizes are consistent with corresponding T=1 and T=3 icosahedral symmetries. Although some SVs are known to modulate symptoms induced by their helper virus, the possible effects of SV-MWLMV on MWLMV infections have not been reported.

Symptoms and Transmission

Symptoms induced by tombusviruses range from mild to severe, depending on the host. Local effects at sites of infection include chlorotic or necrotic lesions, or mosaic patterns. TBSV infections of tomato plants cause mottling and crinkling of infected leaves, along with stunted growth. Infections that go systemic result in necrosis of apical leaves and cause deformation and necrosis of fruit. Aureusvirus infections range from symptomless, such as infections of pothos plants by PoLV, to systemic mottling and fruit streaking in cucumber infections by Cucumber leaf spot virus (CLSV). Maize infected with the MNeSV zeavirus initially exhibit pale green or yellow spots and streaks on leaves. But, as the infection progresses, the chlorotic bandings expand and merge on leaves and stalks, with some areas becoming necrotic.

Both tombusviruses and aureusviruses accumulate to high levels in infected plants and, as soil-borne viruses, are readily transmitted to healthy plants grown in virion-containing soil. Other means of natural transmission for certain members also include seed and pollen transmission. A biological vector has been identified that actively spreads certain members of both of these genera. The root-associated fungus *Olpidium bornovanus* is able to transmit the tombusvirus CuNV and the aureusvirus CLSV to healthy plants. This process has been studied extensively in CuNV and results revealed that the capsid protein is the viral determinant of transmissibility. Outer capsid residues in CuNV particles are able to interact with glycoproteins on the surface of the zoospore. Subsequent plant invasion, mediated by encystment of virus-tethered zoospores, results in virus transfer into root tissue.

No biological vectors for zeaviruses have been identified to date, although different potential candidates have been tested; including select aphids, leafhopper, planthopper, and beetles. Mechanical laboratory infection of maize plants is accomplished by performing vascular puncture inoculation, because traditional rub-inoculation of leaves that works for most tombusvirids is not effective.

Host Range and Geographic Distribution

Natural infections of different tombusvirus species are generally limited to a few hosts. Examples of such natural hosts can be gleaned from the names given to species which, for most viruses, correspond to the plant from which they were first isolated (Table 1). However, not evident from this list is the ability of some species, such as TBSV, to infect cherry and other woody hosts. Aureusviruses infect a range of herbaceous hosts, ranging from vegetable fruits, such as cucumber, to monocots, like wild grasses and cultivated maize. Zeaviruses also infect maize, however as a relatively newly discovered genus, the existence of additional natural hosts remains to be explored.

The distribution of tombusviruses is wide and includes locations in North and South America, different regions in Europe, Algeria, as well as Mediterranean areas. Reports of aureusvirus infections include countries such as Italy, Great Britain, Greece, Jordan, Bulgaria, and India. Zeaviruses were first identified in infected maize in Arizona USA, and since then there have been no additional reports. Collectively, members of the tombusvirus-like group can be considered to be dispersed worldwide.

Applied Aspects

Tombusviruses have been used as expression vectors for the efficient production of foreign proteins in plants. For example, antigens of HIV have been produced using different strategies. A complete protein was expressed by replacing the capsid protein ORF of TBSV with that of HIV p24 capsid protein. In an alternative approach, a peptide epitope of gp120 was displayed on the surface of TBSV particles by fusing its corresponding nucleotide sequence to the 3'-end of the capsid protein ORF. In both of these cases, the foreign protein and modified particle were produced in plants. A related tactic, using insect cells, was used to explore developing a potential vaccine for the poison ricin. Virus-like particles (VLPs) were produced using a baculoviral vector encoding the TBSV capsid protein containing a C-terminally fused ricin peptide. This position in the capsid, *i.e.*, an extension of the P-domain, allowed for optimal presentation of 180 copies of this epitope on the surface of particles. For all cases described above, the proteins or particles were found to be immunogenic and elicited corresponding antibody production. Though still in the proof of concept stage, such products could potentially be useful for vaccine production and diagnostics.

Whether protein expression occurs via virus vectors or agrobacterium-mediated schemes, in whole plants or plant cell suspension cultures, a common obstacle faced in producing optimal levels of a foreign protein is the plant gene silencing system. Overexpression of exogenous mRNAs often leads to targeting and degradation of these messages by this antiviral system. It has been shown, in different production schemes, that these negative effects can be mitigated by co-expressing p19. Depending on the system, doing this can increase yields of the foreign protein by a modest ~20% to over fivefold. Accordingly, further exploration of the utility of this gene silencing suppressor in helping to maximize yield in different large-scale protein production schemes appears warranted.

Another emerging field in which tombusviruses are being employed is nanoparticle technology. The existing nanoscale of self-ordering virus particles makes them attractive candidates for further manipulation. Reengineering of their structural features, such as size and physicochemical properties, can convert them into nanoscaffolds, nanocontainers, or nanobuilding blocks. Genetic and chemical manipulations of TBSV capsids have generated virus-based nanoparticles capable of being chemically derivatized or encapsulating cargo. Additionally, skeletonized TBSV particles have been assembled using multiple copies of a peptide that is a key structural feature that interconnects full-sized capsid subunits in wild type particles. Such designer nanoparticles could be utilized for a variety of purposes, ranging from molecular medicine to biomaterial science. For human applications, safety is an obvious concern, and the effects of TBSV-based nanoparticles on different biological systems is currently being assessed.

Concluding Remarks

Tombusvirus-like viruses are distributed throughout the world and can cause damaging diseases in important crops. Tombusviruses, in particular, have served as excellent model systems to understand different steps in their reproductive cycle. Indeed, members of this genus are among the best characterized plus-strand RNA viruses at the molecular level. Virion analysis has yielded novel information on particle structure and function. Studies of other viral proteins have revealed diverse and critical roles for these viral gene products. Functional analyses of viral RNA genomes have uncovered a remarkable network of intragenomic RNA-RNA interactions that regulate a variety of viral processes. This knowledge, combined with the identification of a multitude of host factors, both protein and lipid-based, has provided an extraordinarily detailed understanding of many steps in virus reproduction. Some infections have been found to contain subviral RNAs that can modulate helper virus levels and disease progression. Among these, DI-RNAs have been particularly useful tools for identifying and studying RNA elements and protein factors involved in viral RNA replication. At an applied level, tombusviruses are also being explored for use in different areas of biotechnology, such as vaccines and nanoparticle development. Future studies of this group of viruses, at both the basic and applied levels, will undoubtedly reveal other fundamental properties and uncover additional useful traits.

Glossary

Citopathology The study of the cellular alterations induced by infectious agents.

Dicer Eukaryotic ribonuclease that cuts long dsRNAs and structured ssRNAs into ~20–25 bp fragments with 2-nt 5′ extensions that activate RISC (see below).

Frameshift A change of the reading frame, which results in a different translation and a different protein product.

Plasmodesmata (Singular: plasmodesma) Channels traversing the plant cell walls, allowing for the cell-to-cell transport of substances. Plasmodesmata are internally coated by the endoplasmic reticulum.

PTSG Post-transcriptional gene silencing; rapid degradation of cellular mRNAs or vRNAs triggered by siRNAs or cellular microRNAs (miRNAs).

Readthrough Readthrough consists of the “translation” of a stop codon, such that the synthesis of a larger protein is

allowed. It is a common phenomenon in viruses, and it has a regulatory function.

Riboviria A higher taxonomic rank including all viruses possessing an RNA genome.

RISC RNA-induced silencing complex; a eukaryotic multiprotein complex that recognizes single stranded microRNAs or double-stranded siRNAs to initiate the destruction of cellular mRNAs or double-stranded viral RNAs.

Silencing suppressor (Suppressor of silencing): Virally encoded proteins from diverse families that interfere with host production or effectiveness of siRNAs.

siRNAs Small interfering RNAs or silencing RNAs, 20–25 bp dsRNAs with two-nt 3′ overhanging ends that target invading viral RNAs or cellular RNAs for degradation in eukaryotic cells.

Tombusvirid Member of the family *Tombusviridae*.

Classification

Realm Riboviria, Kingdom Orthornavirae, Phylum Kitrinoviricota, Class Tolucaviricetes, Order Tolivirales, Family Tombusviridae, Subfamilies Calvirusirinae, Procedovirinae, Regressovirinae.

Taxonomy, Phylogeny and Evolution

The members of this family all have uncapped positive sense, single-stranded RNA [(+)ssRNA] genomes that are encapsidated in icosahedral virions and are related by the similarities of their RNA-dependent RNA polymerases (RdRps). The number of genera doubled between 1998 and 2016 and currently consists of 16 genera assigned to three subfamilies ([Table 1](#)). The increase occurred by subdivision of two genera (*Carmovirus* and *Necrovirus*), incorporation of genus *Umbravirus*, discovery of new unique species, and the availability of complete genome sequences of earlier members. Genus *Umbravirus* is the only genus in the subfamily *Calvirusirinae* (from the Latin “*calvus*”, naked). Umbraviruses have monopartite genomes that use a – 1FS mechanism to express their RdRps but lack a coat protein (CP) gene. The subfamily *Procedovirinae* (from the Latin “*procedo*”, go ahead) contains 14 genera and six species unassigned within the subfamily. These viruses possess a monopartite genome and use a stop codon readthrough (RT) mechanism for the expression of the RdRp. The subfamily *Regressovirinae* (from the Latin “*regressus*”, step back) contains the genus *Dianthovirus*, the members of which have a bipartite genome and use a – 1FS mechanism for RdRp expression. The continued expansion of genera in the family is partly due to the apparent ability of unrelated tombusvirids infecting the same plant to recombine via exchange of coding regions and/or untranslated regions (UTRs) that may change the host range, leading to

^aNo. sgRNAs; genus demarcation criteria uses number of protein-coding sgRNAs only; protein-coding sgRNAs only for genus demarcation.

speciation. The members of the genus *Luteovirus* (current family *Luteoviridae*) have viruses that encode frameshifting replicases that are phylogenetically similar to dianthoviruses and are likely to be moved into the family *Tombusviridae* in the near future.

This family serves as an excellent example supporting the concept of modular evolution of viruses. The RpRp is the sole shared module binding the family (Fig. 1). Within the limitations of the RdRp, the family is highly variable in the arrangement and expression of the various genes on its polycistronic RNA. While all members of the family have a T = 3 icosahedral virion, members of different genera achieve this structure using two phylogenetically distinct, but related, CP modules. The family has acquired at least three phylogenetically different cell-to-cell movement modules. The sources of the virus suppressor of host gene silencing appear to be equally diverse. In addition, some species within a particular genus have acquired additional unique accessory modules, possibly for transmission by fungal vectors or for host-specific viral movement.

Virion Structure

CP-coding tombusvirids produce non-enveloped virions, consisting of 180 CP subunits with a T = 3 icosahedral symmetry. Virus infections produce virions containing a single copy of their genome ranging in size from 3.6 to 4.8 kb for monopartite species and 5.3 kb for dianthoviruses. Dianthoviruses package one each of the genomic RNAs into one virion via a *trans*-activator (TA) loop on RNA1 binding to a complementary *trans*-activator binding site (TABS) just upstream of the subgenomic RNA (sgRNA) start site of RNA2. Genomic RNA constitutes about 17% of the particle weight.

Although the underlying size and structure of the virions are similar, the members can be broadly subdivided into two groups based on the presence or absence of a protruding (P) domain at the C-terminus of the CP. Viruses in genera containing P domains (*Alphacarmovirus*, *Aureusvirus*, *Avenavirus*, *Betacarmovirus*, *Dianthovirus*, *Gallantivirus*, *Gammacarmovirus*, *Macanavirus*, *Pelarspovirus*, and *Tombusvirus*) produce virions that are 32–38 nm in diameter and display a granular surface. Most of these CP subunits range in size from 35 to 42 kDa, while the avenavirus oat chlorotic stunt virus (OCSV) encodes a 48 kDa CP. The X-ray crystal structures of tomato bushy

Fig. 1 Phylogenetic (distance) analysis of the complete RdRps for all sequenced tombusvirids plus selected viruses from the family *Luteoviridae* (turquoise box). Alignments of the 78 sequences were made using MUSCLE while trees were generated with the Maximum Likelihood (ML) algorithm of Mega7 using 1000 bootstrap replicates (showing values >50%). Positions with <50% site coverage were eliminated, leaving 809 positions in the final dataset. Condensed triangles mark monophyletic lineages. Brackets connecting tombusvirid branching, enamovirus plus polerovirus branching, and HCV RdRp (aa 2421–3011) were proportionately shortened. *Tombusviridae* subfamily names are on the right, and colored boxes enclose member genera. Species names are in [Table 1](#).

stunt virus (TBSV) and turnip crinkle virus (TCV) revealed the discrete organization of each CP subunit, and virion structures for many additional species have confirmed the structures for both types of CPs. Generally, the CP subunit can be divided into four domains: the RNA-binding (R) domain is located at the N-terminus followed by the arm (a), shell (S), and P domains (66, 35, 67, and 110 aa, respectively, in TBSV). The R domain contains many basic residues and is found in the interior of the virion. Cryo-electron microscopy reconstructions have further revealed the presence of internal ordered cages of RNA intertwined with CP residues from the R domains beneath the virion surface. This internal scaffold may play a role in directing specific packaging of viral RNA and formation of the icosahedral virions. The virion structure is primarily formed by the globular S domains (stabilized by a pair of Ca^{2+} per subunit) which are composed of two sets of four-stranded antiparallel β -sheets. The S domain is also the most highly conserved region of the CP subunit. There is a flexible hinge of five residues between the S and P domains that allows the CP subunit to adopt different configurations by varying the angle between the domains. This feature of the CP subunit overcomes the structural constraints imposed by the icosahedral morphology. P domains (containing antiparallel β -sheet structures in a jellyroll conformation, with one six-stranded β -sheet and one four-stranded β -sheet) of adjacent CP subunits dimerize to produce 90 projections leading to the granular surface texture. Genera lacking the P domain (*Alphanecrovirus*, *Betanecrovirus*, *Machlomovirus*, *Panicovirus* and *Zeavirus*) produce virions that are 28–32 nm in diameter with a smooth surface similar to viruses in the genus *Sobemovirus*. These smaller CP subunits range from 25 to 30 kDa in size. In natural infections, umbravirus RNA is encapsidated separately within their helper-virus CPs to produce virions of ~30 nm, similar in structure and size to tombusvirids encoding small CPs.

Due to the quasi-equivalent nature of the CP subunits when arranged in an icosahedron, each subunit can take on one of three distinct conformations, termed A, B, and C (respectively, blue, red, and green in [Fig. 2](#)). The A and B conformations differ in the angle between the S and P domains and their arrangement on the virion surface (A: fivefold axes, B: threefold axes). The C conformation

Fig. 2 Virion images based on X-ray crystal structures. (Left) Representation of a particle of tobacco necrosis virus (TNV) at 2.25 Å. The capsid protein of this virus does not contain a protruding domain and is representative of the species in the genera *Alphanecrovirus*, *Betanecrovirus*, *Machlomovirus*, *Panicovirus*, *Umbravirus*, and *Zeavirus*. (Right) Representation of a particle of tomato bushy stunt virus (TBSV) at 2.9 Å. The capsid protein of this virus contains a protruding domain and is representative of species in the remaining genera. For both particles, the individual subunits are colored according to their various conformations: A (blue), B (red), and C (green). From Shepherd, C.M., Borelli, I.A., Lander, G., *et al.*, 2006. VIPERdb: A relational database for structural virology. *Nucleic Acids Research* 34 (Database Issue), D386–D389.

differs from A and B in that their R/a domains intertwine to form an ordered internal structure around threefold axes of symmetry termed the β -annulus. The three different CP subunit conformations pack together as either AB or CC dimers in the virion particle. For TCV, virion assembly initiates with three CP dimers and viral RNA followed by formation of the virion shell according to structural constraints imposed by CP/RNA interactions. In TCV, the origin of assembly RNA sequence (which specifically initiates the interaction with CP subunits) is contained within a 186 nt region at the 3' end of the CP ORF. Assembly studies with TCV also showed that only RNAs equal to or smaller than 4.35 kb in size could be packaged, suggesting very strict size limitations for icosahedral virions.

Virions of tombusvirids have a Mr of $\sim 5.7\text{--}9.1 \times 10^6$ and produce a single, well-defined band upon centrifugation with sedimentation coefficients ranging from 118 to 140 $S_{20,w}$. Virion densities range from 1.34 to 1.36 g cm^{-3} in CsCl gradients. Virus particles are stable at acidic pH, but expand above pH 7 and in the presence of ethylenediaminetetraacetic acid. They are resistant to elevated temperatures, although thermal inactivation usually occurs above 80°C. Due to the lack of a lipid membrane, virions are insensitive to organic solvents and nonionic detergents with the exception of umbraviruses, which lack a CP ORF. In the absence of the assistant virus, plants manually inoculated with the umbravirus genome produce lipid-containing ribonucleoprotein structures, which are sensitive to organic solvents.

Genome Organization and Replication Strategy

The unifying genomic feature is the presence of an interrupted ORF for the virally encoded replicase at the 5' end of the genome with identical aminoacyl termini: a high copy replicase-associated protein (RAP) and the larger RdRp, containing the GDD (glycine aspartate) active site motif of supergroup-II RdRps. Both proteins are indispensable for virus RNA (vRNA) replication. In all members but maize chlorotic mottle virus (MCMV), the replicase gene is the most 5' ORF. Thus, incoming vRNA serves as the mRNA for RAP and RdRp. All genes downstream of the RdRp ORF are expressed from 1 or 2 sgRNAs (see [Table 1](#) and [Fig. 3](#)), which is one of the discriminating characteristics that define genera. These polymerase subunits share a high degree of sequence similarity within the family. Notably, they do not contain a helicase-type motif and the genomes do not encode any helicase-like ORF. ORFs downstream of the polymerase are expressed via 3' co-terminal sgRNAs with the resident ORFs arranged with an assortment of translational strategies such as ribosomal scanning and frameshifting. The single CP ORF is located either internally (tombusviruses, aureusviruses, and zeavirus) or in the 3'-terminal region of the genomic RNA ([Fig. 3](#)). Tombusvirid genomes also encode one or more movement proteins (MPs) that are involved in cell-to-cell spread of the virus. These range in size from the 34–35 kDa version produced by dianthoviruses to the 21–22 kDa proteins expressed by tombusviruses, aureusviruses and maize necrotic streak virus (MNeSV), and down to the 6–9 kDa pair of peptides found in carmo-like and necro-like viruses. Although no mutational analyses of OCSV have been reported, it is likely that the single 8 kDa protein gene overprinted in the CP ORF encodes an MP. In most cases, the MPs can potentiate the local movement (cell-to-cell) of unencapsidated viral RNA but systemic infection

Fig. 3 Genome organizations for type species of family *Tombusviridae*. Genomes are arranged in the same order as in Fig. 2. Genus name (left) and acronym (right) of type species are shown. Genome lengths (heavy black lines) are proportional, and ORFs are color-coded for protein homology. Subgenomic RNAs are thin black lines below the genomes. Stop codon readthrough (arrowhead), frameshift (bent arrow), and noncanonical start codon (asterisk) locations are black symbols. Below the genomes, functions of gene products are identified by color-coded boxes. 30k supergroup MPs are related to tobacco mosaic virus 30 kDa movement protein.

generally requires encapsidation. The exception is for tombusviruses which can infect systemically without CP, albeit at a reduced rate. The other prominent protein product with a clearly defined function is the tombusvirus p19 protein which is a potent suppressor of PTGS. p19 binds siRNAs that are generated by a Dicer-like RNase as part of the host RNA-silencing response to viral infection. This binding prevents incorporation of the siRNAs into the RNA-induced silencing complex (RISC) to prevent further cleavage of viral RNAs. Similar to the function, structure, and mechanism of p19, aureusvirus p14 binds siRNAs, albeit less specifically. Although other members of the family may not encode a unique suppressor protein, it is known that other proteins can have suppressor activity aside from their primary functions. This is the case for TCV where the CP is the viral suppressor of PTGS. Various additional ORFs are also encoded in some tombusvirids with undefined functions. One other method utilized by tombusvirids for gene expression is genome segmentation which is only employed by dianthoviruses where RNA2 is monocistronic and encodes the MP.

Additional ORFs have been identified in the genomes of panicoviruses and MCMV. For the panicovirus PMV, the unique p15 ORF overprinted within the CP ORF is not necessary for replication but is required for systemic infection along with the CP. For the closely related MCMV, the unrelated ORF overprinted within its CP ORF is required for efficient systemic infection.

Since the genomic RNAs are positive sense, they are directly infectious as unencapsidated RNAs. vRNAs lack a 5' cap structure and the 3' ends are not polyadenylated nor do they form tRNA-like structures. Instead, tombusvirids and the closely related viruses in the luteovirus genus form several different types of complex structures at their 3' ends called cap-independent translational enhancers (3'CITEs) that interact with small or large stem loops (SLs) usually in the 5'UTRs of vRNA or sgRNAs to allow the circularization that is typically accomplished by recruitment of eukaryotic translation initiation factors (eIFs) that bind to poly(A), 5' caps, and ribosome subunits to initiate translation.

Various 3'CITEs have been identified in tombusvirid genomes; the barley yellow dwarf virus (BYDV)-like 3'CITE (BTE) of tobacco necrosis virus (TNVD), the panicum mosaic virus (PMV)-like 3'CITE (PTE) of panicoviruses and cucumber leaf spot virus (CLSV), the Y-shaped 3'CITE of TBSV and carnation Italian ringspot virus (CIRV), the PTE variant of MCMV, and the smaller I-shaped 3'CITE of the zeavirus MNeSV which is also present in some aureusviruses and carmo-like viruses. The 3'CITEs have different structures and binding properties. The direct translation readthrough or frame-shift strategies ensure that the RdRp active site is present in only 5%–10% of the vRNA translation products since readthrough and frameshifting are inefficient. Translation of both RAP and RdRp subunits is followed by localization to and proliferation of cellular membranes. The location of viral replication varies depending on the particular virus and is specified by the pre-readthrough portion of the polymerase (see Cytopathology). In all cases studied to date, the polymerase anchors on membranes, causing proliferation. The advent of yeast-based replication systems for four tombusviruses i.e. CIRV, TBSV, cucumber necrosis virus (CNV) and cymbidium ringspot virus (CymRSV) has provided valuable insights into the host components utilized by the viral replication complex.

Once the polymerase has been assembled, it binds to the 3' terminus to initiate minus-strand synthesis. If full-length copies are generated, these serve as templates for synthesis of progeny genomic RNAs. This synthesis is highly asymmetrical with (+) RNA accumulating at much higher levels than (–) RNA. This is controlled by a small base-pairing interaction between a structure at the extreme 3' end of vRNAs and sgRNAs. These are the replication silencer element (RSE) and a 3'-complementary silencer sequence (3'CSS) present in a bulge ~50–60 nt upstream which sequesters the 3' end from the RdRp. Occasionally, positive-strand synthesis will be terminated prematurely which leads to the formation of templates for plus-strand sgRNA synthesis. This premature termination is controlled by long-distance RNA–RNA interactions which occur *in cis* for monopartite tombusvirids such as TBSV, or *in trans* for dianthoviruses via the same TA/TABS base-pairing interaction used to ensure encapsidation of both RNAs inside one virion. Generally, sgRNAs are produced later in the infection cycle and behave as monocistronic mRNA or polycistronic RNAs, depending on the genus. The sgRNAs demonstrate various translational strategies such as ribosomal scanning to express the p19 ORF which is nested within the p22 ORF in TBSV. In this case, the p22 start codon is suboptimal and is occasionally read through by ribosomes before initiation at the optimal p19 start codon. MNeSV and aureusviruses express their silencing suppressor ORFs using the same mechanism. Similar ribosomal scanning past suboptimal start codons express one or more of the downstream ORFs of carmo-like viruses and necro-like viruses.

Very small noncoding viral RNAs that are coterminal with the parent virus 3' end have been identified in infections of MCMV, TCV, CNV, TNVD, and the three dianthoviruses red clover necrotic mosaic virus (RCNMV), carnation ringspot virus (CRSV), and sweet clover necrotic mosaic virus (SCNMV). RNase analyses of RNA fragments from the 3' UTRs of RCNMV, MCMV and the umbravirus opium poppy mosaic virus (OPMV) using Xrn1 *in vitro* identified a conserved pseudoknot in the 3'UTR that protects the RNA from further 5'-3' degradation. For RCNMV and TNVD, these were shown to be generated by the host 5'-3' exoribonuclease Xrn4, which is stalled by RNA secondary structure. The function of these small RNAs is not yet fully clarified. Sequence searches for program-predicted exoribonuclease-resistant RNAs (xrRNAs) followed by *in vitro* analyses identified additional Xrn-blocking structures in the 5'UTR of most umbravirus sgRNAs.

Life Cycle

For most genera, infection is initiated either by mechanical inoculation (piercing of leaf or root tissues with virus-contaminated material) or via vector transmission by a fungal vector in roots. For umbraviruses natural infections occur via viruliferous aphids in the presence of the umbravirus helper virus. After the virus enters an epidermal cell, the virion disassembles, and vRNA engages ribosomes and translation factors to synthesize RAP and RdRp. When enough newly-synthesized vRNA accumulates in initially infected cells, vRNA is transmitted via their MP(s) through plasmodesmata to neighboring cells for further rounds of replication and spread cell-to-cell. At some point newly assembled virions can move throughout the plant via vascular tissue, to produce systemic infections. Viruses can survive in debris and soil for a long time before a new infection cycle starts.

Cytopathology

Plants infected with tombusvirids display a distinctive cytopathology, observed by electron microscopy as dense-staining features. Depending on the genus, different virus species can replicate on, remodel, and proliferate membranes of peroxisomes, mitochondria and/or the cortical ER. The hallmark of infections by members of the genus *Tombusvirus* are the cytopathic structures known as multivesicular bodies, which are generated after the virus-induced progressive vesiculation and invagination either of the limiting membrane of peroxisomes or the outer membrane of mitochondria. The vesicles are believed to be sites of viral replication. Exceedingly high concentrations of progeny virions can accumulate in the multivesicular bodies, but are also arranged to form crystals in the cytoplasm.

Subviral Molecules

Three different types of subviral entities are associated with the replication of members in the family *Tombusviridae*: satellite viruses, satellite RNAs (satRNAs) and defective interfering (DI) RNAs. All depend on the presence of a helper virus for their replication, movement, and transmission and may affect helper virus infections. Whereas DI RNA sequences are identical to those of the helper genomic RNAs, satellite viruses and satRNAs share no or limited sequence identity with their cognate viruses. Satellite viruses code for their own CP. In most cases satRNAs are encapsidated by the helper virus-encoded CP, but satC and satS, which are only found in plants infected with PMV and satPMV, are encapsidated by satPMV CP.

Satellite viruses described so far are supported by viruses in the genera *Alpha*- and *Betanecrovirus* (Satellite tobacco necrosis virus, STNV), *Panicovirus* (Satellite panicum mosaic virus, SPMV) and *Aureusvirus* (Satellite maize white line mosaic virus, SMWLMV), and are classified in their own genera *Albetovirus*, *Papanivirus* and *Aumaivirus*, respectively. Satellite viruses associated with tombusvirids possess an uncapped (+) ssRNA genome of ~0.8–1.2 kb, lack a poly(A) tail, and harbor a single ORF that encodes their own CP. The subunits are arranged in a T = 1 lattice, and some satellite viruses (SPMV) harbor signals for specific packaging of the satellite virus genome, while STNV1 packaging appears to be mostly related to the abundance of appropriate-sized RNAs. As mentioned above, satellite virus particles are readily distinguished from the helper virions, due to their different size.

The STNV genome can form secondary structures for specific recognition by the helper virus RdRp, and contains a 3'-translational enhancer domain (TED) which enhances translation by interacting with a short nucleotide stretch in the 5'UTR. STNV can attenuate the symptoms induced by its helper virus, probably by competing for factors essential for replication. Conversely, SPMV results in a severe exacerbation of PMV-induced symptoms, often leading to plant death, probably due to synergy with the helper virus and to a cytotoxic effect exerted by the satellite CP. Whereas SPMV has the smallest known satellite virus genome, SMWLMV is characterized by the largest satellite virus CP. No effect on the helper virus symptomatology for SMWLMV has been reported.

The origin of nonhomologous satRNAs is unclear at present, but they can be generated from recombination events with other satRNAs, the viral genome, DI RNAs, or host sequences. Generally, satRNAs associated with tombusviruses do not share sequence homology with their helper viruses, except for the four satRNAs associated with tombusviruses, which have short conserved nucleotide stretches at the 5' and 3' ends, in addition to a ~50 nt sequence in the 5'-terminal region, in common with genomic and DI RNAs. Also the satRNAs (C, D and F) associated with the betacarrovirus TCV have a conserved heptanucleotide at the 3' end. In addition, whereas satRNA D and satRNA F are true satRNAs, satRNA C is a recombinant between satRNA D (5' region) and TCV (3' region). Other tombusvirids are also known to harbor satRNAs, like the 615-nt satRNA associated with the betanecrovirus beet black scorch virus (BBSV) and the satRNAs reported in association with umbraviruses. All the satRNAs described so far have high levels of secondary structure, which account for their stability and survival. Some predicted structures are conserved and are important for the recognition and replication of these molecules by the helper virus. The effect on virus-induced symptomatology is variable. SatRNA C enhances TCV symptoms, whereas satRNA D and F do not interfere with TCV symptomatology. BBSV satRNA exacerbates its cognate virus symptoms. The four 600–800 nt satRNAs associated with tombusviruses differently influence the viral symptoms: the satRNA associated with CyRSV and TBSV satRNAs B1 and L do not modulate the helper virus infection, whereas TBSV satRNA B10 attenuates symptom expression. The satRNAs associated with the umbraviruses groundnut rosette virus (GRV) and tobacco bushy top virus (TBTv) are essential for the encapsidation and transmission of their helpers by an assistant virus.

Many tombusvirids generate DI RNAs that can affect pathogenesis. DI RNAs are essentially small, non-coding deletion mutants of the viral genome which are generated by errors in replication such as rearrangement or recombination. Recombination can occur between both homologous and nonhomologous sequences, probably by a copy-choice mechanism in which the viral RdRp jumps from one template to another during the replication process. They usually consist of genomic-derived 5' and 3' non-coding sequences and some internal regions, which are essential for their replication by the virus' RdRp. DI RNAs are more readily generated at high multiplicity of infection. Several species such as TBSV and TCV produce DI RNAs during viral infection. For TBSV the presence of DI RNAs results in attenuation of symptoms, whereas for TCV the presence of DI RNAs intensifies symptoms. The attenuation of symptoms is not only due to competition for host factors, but largely resides in the highly structured DI molecules, which can trigger post transcriptional gene silencing against the helper virus genome.

Both DI RNAs and satRNAs have been useful molecular tools for studying viral replication and recombination. Since both satRNAs and DI RNAs are dependent on the host or parent virus for replication, they must retain any sequence or structural signals required for recognition by the viral polymerase, and therefore can help determine those signals.

Recombination can facilitate viral evolution as well as repair of viral genomes, so it is an important factor in the virus life cycle, and it can have profound effects on pathogenesis. In the tombusvirus family, recombination in the carmo-like and tombus-like viruses has been shown to repair damaged or deleted 3' ends of virus-associated RNAs, as well as generate new satRNAs or DI RNAs.

Pathogenesis

Depending on the host and on the genus, tombusvirid infections can be symptomless or consist of mottling, crinkling, mosaic, distortion, chlorotic and/or necrotic lesions on the leaves, and stunting of the plants. The natural host range of most species is relatively narrow; however, the experimental host range tends to be broad. Members can naturally infect either monocotyledonous or dicotyledonous plants. Fewer tombusvirids infect monocots: eight infect grasses (Family Poaceae) while four infect members of the Order *Asparagales*. Natural infections can be limited to or are often concentrated in the root system. Many species are found in the soil, where

they survive for a long time. All species are readily transmitted by host vegetative propagation and mechanical inoculation (although some species cannot be inoculated by leaf-rub inoculation), and some may be transmitted by contact and through seeds. A number of species are readily detected in surface waters, rivers, lakes, and even the ocean. Transmission by chytrid fungi in the genus *Olpidium* and by beetles has also been reported for members of several genera. For viruses that can be transmitted by fungi, there is a considerable amount of specificity required between the virus and the fungal vector. For example, the tombusvirus CNV, the gammacarmovirus melon necrotic spot virus (MNSV), and the aureusvirus CLSV are transmitted by the root-inhabiting chytrid fungus *Olpidium bornovanus*, whereas the alphacarmovirus TNVA, and betanecroviruses TNVD and BBSV are transmitted exclusively by *Olpidium brassicae*. Umbraviruses are aphid-transmitted, but only when plants are co-infected with an “assistant” luteovirid. Many members can be transmitted through the soil either dependent on, or independent of, a biological vector. This rather unusual soil and water mode of transmission is unique to this plant virus family and is based on the unusually robust constitution of the virion.

Geographical distribution of particular species varies from wide to restricted and is strongly linked to the presence of the specific host. Most species occur in temperate regions although legume-infecting gammacarmoviruses and furcraea necrotic spot virus (FNSV) have been found in tropical areas. Two alphacarmoviruses occupy more extreme environments: Nootka lupine vein clearing virus (NLVCV) grows in Alaska, USA (northern temperate climate above the arctic circle), and saguaro cactus virus (SgCV) was found in a hot desert in Arizona, USA. MCMV was initially found in South America, but it is now one of the most widespread family members due to the extreme increase in maize (*Zea mays*)-producing nations throughout tropical and temperate zones.

Glossary

Cleavage Processing of large proteins into smaller peptides at specific amino acid sequences by proteases.

Motif A short amino acid or nucleotide sequence that is presumed to have a biological function through sequence-specific binding.

Polyprotein A large protein with a chain of covalently joined smaller peptides that can be cleaved by virus-encoded proteases into smaller proteins with different biological functions.

Virion The protective shell of genomic RNA/DNAs of viruses covered mostly with virus-encoded capsid and often with other virus-encoded accessory proteins.

Introduction

The members of the genus *Tritimovirus* have previously been included in the genus *Rymovirus* based on biological properties such as monocotyledonous hosts and transmission by eriophyid mites. However, phylogenetic studies based on partial or complete genome sequences of *Rymovirus* members revealed that the eriophyid mite transmission characteristic was a paraphyletic trait within the genus *Rymovirus*. Hence, Wheat streak mosaic virus (WSMV) and Brome streak mosaic virus (BrSMV) were separated from the genus *Rymovirus* and classified into the new genus *Tritimovirus* with WSMV as the type species. Subsequently, four other definitive species were assigned to the genus *Tritimovirus*. Among the members of genera *Tritimovirus* and *Rymovirus*, WSMV is the most economically important virus on wheat in most wheat growing regions of the world, causing significant yield losses. WSMV was first reported from Nebraska, USA as wheat mosaic disease, and disease caused by WSMV was referred as wheat streak mosaic disease (Fig. 1).

Taxonomy and Classification

The family *Potyviridae* contains a total of ten genera, plus three unassigned species, and includes *Tritimovirus* and *Rymovirus* as distinct genera. Some members of the *Rymovirus* and *Tritimovirus* genera are transmitted by eriophyid mites *Abacarus hystrix* (Nalepa) and *Aceria tosichella* (Keifer) (Fig. 2(A)), respectively; however, members of *Rymovirus* are phylogenetically more related to aphid-transmitted members of the genus *Potyvirus*. Recently, there was an unsuccessful proposal to assimilate the genus *Rymovirus* into the genus *Potyvirus* as a rymovirus subgroup based on phylogenetic relatedness. Currently, the genus *Rymovirus* consists of three known definitive members (*Agropyron mosaic virus*, *Hordeum mosaic virus*, and *Ryegrass mosaic virus*) with *Ryegrass mosaic virus* (RGMV) as the type species, while the genus *Tritimovirus* consists of six recognized species (*Brome streak mosaic virus*, *Oat necrotic mottle virus*, *Tall oatgrass mosaic virus*, *Wheat eglid mosaic virus*, WSMV, *Yellow oat grass mosaic virus*) with *Wheat streak mosaic virus* as the type species (Table 1).

Virion Structure

Virions of *Tritimovirus* and *Rymovirus* members are flexuous filaments of 690–720 nm in length and 11–15 nm in diameter (Fig. 2(B)) made up of 95% protein and 5% RNA. The molecular weight (MW) of rymo- and tritimoviral CP subunits range between 27 and

39 kDa (Table 1) with differences mainly due to variable lengths at the N-terminal region. The internal core of the CP residues is likely involved in virion architecture. The N- and C-terminal aa are exposed on the surface of the viral particles, and these exposed aa most likely interact with other viral, host, and vector proteins to successfully complete the virus life-cycle. The conserved N-terminal DAG-motif found in potyviral CPs that is required for aphid transmission is not present in most rymo- and tritimoviral CPs.

The helical virion assembly of WSMV suggests that each virion particle possesses ~2000 CP subunits surrounding the RNA with 7–8 subunits per turn. The aa sequence suggests the MW of WSMV CP to be 37 kDa; however, SDS-PAGE predicts the molecular weight to be 45 kDa. Partially purified virions of WSMV resolved into a 45 kDa major CP, plus 32 and 29 kDa minor CP bands. These minor proteins are part of the 45 kDa CP. The exact nature of the production of these additional CP bands is not known. However, these bands are thought to be produced due to proteolytic activity in senescence leaves.

Genome Organization

The genomic organization of *Rymovirus* and *Tritimovirus* members is similar to those in the genus *Potyvirus*. *Rymovirus* and *Tritimovirus* members possess a positive-sense single-stranded RNA (ssRNA) with sizes ranging from 9292 to 9672 nt (Table 1). The genomic RNAs of these viruses likely contain a viral protein genome-linked (VPg) at the 5' terminus and a poly-A-tail at the 3' terminus. The genome encodes a single ORF coding for a polyprotein with 3007 to 3110 aa with a predicted MW of 341–352 kDa protein (Table 1). The polyprotein is processed into mature proteins by three virus-encoded proteinases: P1, HC-Pro and NIa-Pro. The serine proteinase P1 and cysteine proteinase HC-Pro cleave the polyprotein *in cis* at their C-terminal ends, while the serine proteinase NIa-Pro cleaves the polyprotein *in trans* at other heptapeptide cleavage sites. Thus, cleavage of the polyprotein results in 10 mature proteins. An additional small ORF, PIPO, is expressed by the polymerase slippage mechanism from the P3 cistron as P3N-PIPO. The 5' and 3' non-translated regions (NTRs) in all members range from 112–145 and 144–244 nt, respectively (Table 1). The NTRs are predicted to contain the *cis*-acting elements for replication and translation enhancers. The mechanism of genomic RNA translation in rymo- and tritimoviruses is not known. However, translation of genomic RNA potentially takes place through the cap-independent leaky scanning mechanism similar to members of potyviruses.

Functions of Viral Proteins

The mature polyproteins encoded by members of the genera *Rymovirus* and *Tritimovirus* consist of the following proteins from the N-terminus to C-terminus: P1, HC-Pro, P3, P3N-PIPO, 6K1, CI, 6K2, NIa-VPg, NIa-Pro, NIb, and CP (Fig. 3). WSMV is the most extensively studied virus outside the genus *Potyvirus* in the family *Potyviridae*. Hence, functions described for viral proteins in this section are mostly based on studies on WSMV.

The P1 protein is a serine proteinase and is the most divergent among WSMV isolates. The P1 protein of WSMV and Oat necrotic mottle virus (ONMoV) but not Agropyron mosaic virus (AgMV) and Hordeum mosaic virus (HoMV) is a suppressor of RNA silencing and a pathogenicity enhancer (Fig. 3). In contrast to the multi-functional helper component proteinase (HC-Pro) of potyviruses, the HC-Pro from WSMV is dispensable for systemic infection, but it is required for wheat curl mite transmission. WSMV HC-Pro is predicted to be a virus-encoded accessory protein of virion component similar to members of the genus *Potyvirus*. The HC-Pro proteins of AgMV and HoMV of the genus *Rymovirus* are suppressors of RNA silencing. The P3 protein is required for replication, while P3N-PIPO of WSMV is required for cell-to-cell movement. The P3N-PIPO is highly conserved among WSMV isolates and mutating P3N-PIPO without affecting the P3 coding sequence severely debilitates cell-to-cell movement of WSMV.

The exact role of 6K1 in virus biology is not known though deletion of this cistron is lethal to WSMV. The CI protein is the largest of all virus-encoded proteins. CI proteins of rymo- and tritimoviruses possess RNA helicase activity and an ATP binding domain. These domains are predicted to form the viral replication complex. The CI is also predicted to be involved in cell-to-cell movement similar to potyviral CI proteins. The 6K2 is another small peptide present in all rymo- and tritimoviruses and is thought to be involved in viral replication, movement and pathogenicity.

The ~49 kDa NIa protein is cleaved into an N-terminal VPg (~23 kDa) and a C-terminal proteinase (Pro; ~26 kDa) (Fig. 3). The VPg protein is covalently attached to the 5' end of viral genomic RNA and is predicted to act as a primer during replication. VPg is also predicted to interact with host factors for translation, long-distance movement, and symptom development. NIa-Pro, a serine protease, is responsible for the cleavage and release of mature proteins from the polypeptide except for P1 and HC-Pro. The NIa-Pro cleaves *in cis* at its C-terminus for its own release from the polypeptide, followed by *in trans* cleavage at specific heptapeptide cleavage sites. The NIa-Pro of WSMV was identified as an elicitor of superinfection exclusion. NIa and NIb proteins form inclusion bodies in the nucleus, hence the name 'nuclear inclusion' for these proteins. The NIb protein is an RNA-dependent RNA polymerase (RdRp) and is responsible for viral replication through interactions with other viral and host proteins.

The C-terminal product of the polyprotein is the CP with multifunctional roles. The CP, in addition to virion encapsidation, is also involved in wheat curl mite transmission, cell-to-cell and long-distance movement, pathogenicity, and superinfection exclusion (Fig. 3). The C-terminal region of WSMV CP is dispensable for virion assembly, but it is required for cell-to-cell movement. The CP aa 36–84 are dispensable for virion assembly and systemic infection, but deletions comprising aa 57–84 elicited more severe symptoms compared with wild type virus. The CP aa 57–100 are identified as viral determinants along with HC-Pro for wheat curl mite transmission.

Fig. 3 Schematic representation of genomic organization of Wheat streak mosaic virus (WSMV). The large rectangle indicates an open reading frame encoding a large polyprotein that is cleaved *in cis* by P1 and HC-Pro (indicated with curved arrows). The remainder of the polyprotein is predicted to be cleaved by Nla-Pro (indicated with upward arrows) *in cis* at its C-terminal end and *in trans* between P3/6K1, 6K1/CI, CI/6K2, 6K2/Nla-VPg, Nla-VPg/Nla-Pro, Nla-Pro/Nib, and Nib/CP at heptapeptide cleavage sites. Boxes below the genomic organization indicate proteins encoded by WSMV and their putative functions in virus biology.

Life Cycle and Epidemiology

Host Range

The known host range of rymo- and tritimoviruses is restricted to monocotyledonous plants including several cereals and other grass species. Among members of rymo- and tritimoviruses, the host range of WSMV has been most extensively examined. Wheat (*Triticum aestivum*) and corn (*Zea mays*) are the most important hosts for WSMV, but natural WSMV infection of corn has been mostly controlled with the introduction of hybrid maize cultivars resistant to WSMV. The host range of WSMV also includes oats (*Avena sativa*), barley (*Hordeum vulgare*), rye (*Secale cereale*), foxtail millet (*Setaria italica*), and proso millet (*Panicum miliaceum*). In addition to cereals, a number of annual and perennial grasses serve as hosts for WSMV. Many of these plants also serve as hosts for wheat curl mite, the vector of WSMV.

Vector Transmission

Some members of both the rymo- and tritimoviruses are transmitted by eriophyid mites. RGMV is efficiently transmitted by the cereal rust mite (*A. hystris*), but this vector also transmits AgMV inefficiently. No vector has been found for HoMV, the third member of the genus *Rymovirus*. The mechanisms and viral determinants of rymoviral transmission by *A. hystris* are not known.

Among members of the genus *Tritimovirus*, WSMV and BrSMV are the only viruses with known vectors, and these two are transmitted by the wheat curl mite *Aceria tosichella* (Keifer) (Fig. 2(A)). Transmission of WSMV has been extensively studied. The HC-Pro and CP of WSMV are identified as viral determinants of mite transmission. Only immature mites can acquire the virus in as little as 15 min with improved transmission efficiencies as acquisition time increases up to 16 h. Mites remain viruliferous through molting and as adults for at least seven days. Thus, WSMV transmission by wheat curl mites is not stylet or foregut borne but exhibits several characteristic features of persistent transmission. However, the short acquisition time and lack of a latent period for WSMV transmission by wheat curl mites are not typical of persistent transmission. This incongruence could be due to the microscopic morphologies of these mites that could impact feeding and internal mite-virus interactions. Overall, WSMV transmission by wheat curl mites does appear to fit the category of persistent transmission with some differences.

The remaining viruses in these two genera have not been associated with a particular vector. Recent work has demonstrated that both *A. tosichella* and *A. hystris* are each a complex of several genetic variants. Some variants within these two species have distinct, sometimes unique, host relationships within the grasses. Additionally, some of these variants have been shown to have differing virus transmission capacity with WSMV, but little is known about the virus capabilities of many of these variants. Further research is needed to delineate the vectors of several of the viruses in these two genera, and perhaps the genetic variants of these two mite species should be considered as potential vectors for these remaining viruses.

Fig. 4 Wheat streak mosaic virus (WSMV) disease cycle in winter wheat. Wheat curl mites disperse from maturing wheat onto summer green bridge hosts; wheat curl mites move from green bridge hosts onto newly emerged wheat seedlings during the fall and transmit WSMV; mites and virus overwinter in winter wheat; as temperature warms up in the spring, virus symptoms develop and impact wheat yield.

Seed Transmission

No information on seed transmission of rymo- and tritimoviruses is available except for WSMV. Seed transmission of WSMV was first reported at 0.1% level in maize in seed production lots from Iowa. WSMV transmission through seed in eight wheat genotypes was reported at 0.2%–0.5%. However, seed transmission of up to 1.5% was reported in individual wheat genotypes. Low seed transmission of WSMV may not be significant in establishing epidemics in areas where the virus is prevalent, but wheat plants infected through seed transmission can serve as a source of virus inoculum for the secondary spread through wheat curl mites. Seed transmission of WSMV is epidemiologically most significant with the possibility of virus spread through global trading and movement of infected seed.

Disease Cycle

In eriophyid mite-transmitted diseases, the bridging of hosts between two cropping seasons plays an important role in continuing the disease cycle. The epidemiology and disease cycle for wheat curl mite-transmitted WSMV have been extensively studied. Knowledge and management of the WSMV disease cycle (Fig. 4) likely apply to other viruses in the genera *Rymovirus* and *Tritimovirus*.

Due to the lack of well-developed legs, wheat curl mites rely on wind currents to disperse within and between the fields. Mites move from the leaves and stems to wheat spikes in headed wheat fields for further propagation and protection. As the wheat crop matures with the drying of heads and foliar tissue, the mites must find new hosts to survive during the summer. This is particularly critical as the mites cannot survive for more than a day or two off a living host. These hosts consist of volunteer wheat, corn and other cereal crops, and summer grasses that form the green bridge for mites and viruses between the summer wheat harvest and emergence of the fall-planted crop. Mites from WSMV-infected volunteer wheat and other cereal and grass hosts can move onto wheat seedlings during the fall season via wind. These mites propagate rapidly due to their rigorous reproductive capacity and transmit WSMV to wheat seedlings. In general, warmer fall conditions, early wheat planting, and presence of a green bridge to host the mites and virus between summer harvest and emergence of the fall crop increase virus epidemics in susceptible wheat cultivars. Overwintering of mites will occur as eggs, larvae, nymphs, and adults in wheat and other plant hosts, and WSMV will survive in

live wheat leaves and crown of virus-infected plants. Serious epidemics result from extensive mite presence and virus transmission occurring through the fall with the most serious symptoms and impact developing with the advent of warm temperatures in the spring. As temperatures warm up in the spring season, mites become active, multiply rapidly, and eventually move to the summer green bridge just before harvest to continue the disease cycle (Fig. 4).

Pathogenicity

Knowledge of how rymo- and tritimoviruses elicit disease is scant except for WSMV. The availability of reverse genetics system for WSMV facilitated the identification of viral determinants involved in disease development. The P1 of WSMV was identified as a suppressor of RNA silencing and a pathogenicity enhancer. Potato virus X infection of transgenic *N. benthamiana* plants expressing WSMV P1 protein resulted in more severe symptoms compared to non-transgenic *N. benthamiana* plants. Wheat plants infected by WSMV with complete deletion of HC-Pro elicited mild symptoms compared with wild-type virus. Surprisingly, WSMV harboring deletions comprising aa 57–84 in CP elicited more severe symptoms in multiple cereal hosts with increased accumulation of viral genomic RNA copies. In members of the genus *Potyvirus*, the 5'- and 3' NTRs have been identified as symptom determinants as mutations in these regions affected symptom severity. However, it is possible that these mutations might have affected viral *cis*-acting elements located in the 5' and 3' NTRs for replication. Additionally, P3, CI, 6K2, and NIa-VPg of different potyviruses have been identified as pathogenicity enhancers. However, no information is available on the role of these proteins in disease development of rymo- and tritimoviruses. Co-infection of wheat by unrelated WSMV and Triticum mosaic virus (TriMV), a *Poacevirus* in the family *Potyviridae*, exacerbates the disease phenotype with enhanced accumulation of both interacting viruses. Interactions between WSMV and TriMV during early stages are asymmetrical because prior infection of wheat by TriMV caused accelerated cell-to-cell movement and genomic RNA accumulation of WSMV but not vice-versa. The mechanisms and viral and host factors responsible for synergistic interaction between WSMV and TriMV are not known.

Diagnosis

The signature pinwheel-shaped inclusion bodies and flexuous filamentous virion particles are diagnostic features of potyviral infections. However, the requirement of sophisticated methodologies and equipment limit the use of these characteristic features as diagnostic methods for potyviruses. Most of the purified virions of rymo- and tritimoviruses are immunogenic in rabbits for the production of polyclonal antibodies. The polyclonal antibodies raised against purified virions have been widely used for the detection of rymo- and tritimoviruses in direct antigen coating, double antibody sandwich, and triple antibody sandwich forms of enzyme-linked immunosorbent assays (ELISAs). ELISA is less expensive and can be used for large-scale detection of samples, but the sensitivities of ELISAs depend on the quality of antibodies. The availability of genome sequences of rymo- and tritimoviruses facilitated the development of RT-PCR and real-time RT-PCR (RT-qPCR) methods for sensitive detection of viruses to overcome the limitations of ELISA-based detection methods. Additionally, multiplex RT-PCR methods allow for the simultaneous detection of multiple viruses. RT-qPCR has been used for absolute quantification of WSMV genomic RNA copies to study virus biology and virus-host, virus-vector and virus-virus interactions.

Disease Management

WSMV is the most economically important virus among eriophyid mite-transmitted rymo- and tritimoviruses. Hence, extensive research on the development of management practices for WSMV in wheat has been performed. Viruliferous mites from over-summering hosts are the primary source of infection. Hence, cultural practices targeted at managing mite populations and deployment of plants resistant to eriophyid mites, viruses, or both are needed for effective management of rymo- and tritimoviruses.

Cultural Practice

Cultural practices developed for the management of WSMV are most likely applicable to other viruses in these two genera, though some fine tuning might be required. Due to the secluded nature of mite feeding, management of wheat curl mites through pesticide application is ineffective. The main cultural management practice for WSMV is the elimination of the green bridge by removing volunteer wheat and other cereals and grasses that host both virus and vector through the summer, thus preventing the disease cycle from continuing into the fall and the next wheat crop. Mite populations are at their peak just before wheat harvest, so any volunteer wheat growing at this time is rapidly infested with mites and if not controlled will serve as an optimal green bridge host for mites and virus. Severe WSMV outbreaks are likely if hailstorms occur prior to wheat harvest and increase volunteer wheat growth. The overlap of emerged winter wheat in the fall with adjacent late-maturing crops such as maize, sorghum and small grain cover crops should also be avoided. These late-maturing crops act as reservoirs for virus and vector. Additionally, avoiding early planting of winter wheat will reduce infestation potential and the period of favorable fall temperatures for mite and virus development. Thus, effective management of WSMV depends on an integrated disease management approach by optimizing cultural practices in combination with genetic resistance.

Genetic Resistance

Except for WSMV, little or no information is available on genetic resistance against rymo- and tritimoviruses. The deployment of genetically resistant wheat cultivars with nonallelic *Wsm1*, *Wsm2*, or *Wsm3* genes has been used for WSMV disease management. Wheat cultivar Mace with the *Wsm1* gene, a single dominant R gene, associated with chromosome 4D from intermediate wheatgrass [*Thinopyrum intermedium* (Host) Barkworth & D.R. Dewey] provides resistance to WSMV and TriMV. The *Wsm2* gene, a single dominant gene, present in wheat cultivars RonL, Snowmass, Clara CL, and Oakley CL is resistant to WSMV but not to TriMV. The *Wsm2* gene is associated with chromosome 3BS with unknown origin. Wheat cultivars with *Wsm1* or *Wsm2* genes provide resistance through temperature-dependent impairment of viral long-distance movement; however, for both of these genes, resistance begins to break down as temperatures increase above 20°C. *Wsm3* is a true resistance gene that is transferred from wheatgrass (*T. intermedium*) to provide resistance against WSMV at higher temperatures. However, commercial wheat cultivars with *Wsm3* gene are not yet available.

Eriophyid mites not only transmit rymo- and tritimoviruses, but they can also cause yield losses in crop plants due to their great reproductive and feeding capabilities. Thus, the development of crop plants resistant to eriophyid mites could minimize losses from viruses as well as feeding damage by eriophyid mites. Thus far, genetic resistance to wheat curl mite has been reported for four curl mite colonization (*Cmc*) genes. The *Cmc1/Cmc4*, *Cmc2*, or *Cmc3* genes in wheat have resulted from DNA transfer from *Aegilops tauschii*, *A. elongatum*, and *S. cereal*, respectively. However, with the extensive deployment of wheat cv. TAM107 (*Cmc3* gene), wheat curl mite populations were able to adapt to this resistance gene. Thus, the durability of genetic resistance against wheat curl mites has been questioned. Wheat cultivars with multiple lines of resistance through gene pyramiding may provide more durable resistance to wheat curl mites. Additionally, pyramiding mite-resistance with virus-resistance could provide an effective management tool.

Mutation of recessive genes encoding the eukaryotic translation initiation factor 4E or its isomers to prevent interaction with viral proteins without being lethal to host plants provides resistance against several members in the genus *Potyvirus*. However, there is no information on recessive resistance against rymo- and tritimoviruses. With the advent of CRISPR-Cas9 technology, mutation of candidate recessive genes in crop plants can be achieved to obtain resistance against rymo- and tritimoviruses.

Biotechnological Application

Plant viruses can be used for the expression of specialty products and for functional genomics of host genes through virus-induced gene silencing. WSMV has an excellent reverse genetics system that can be exploited for recombinant protein expression, vaccine production, and drug delivery as a nano-agent. WSMV has been used to express GUS, GFP, and RFP proteins in wheat to examine virus movement, virus-host, and virus-virus interactions. Lastly, small peptides can be fused to CP or HC-Pro to integrate into virions that can be used for biotechnological purposes.

A major limitation of using plant viruses as expression vectors is the instability of inserted sequences since many plant viruses recombine by deleting all or parts of inserted sequences. However, inserted GFP or RFP in the WSMV genome was stably expressed for more than 120 days with no indication of deletions or reassortment in inserted sequences. Additionally, WSMV stably maintained and simultaneously expressed two foreign genes inserted between the P1/HC-Pro and N1b/CP cistrons for more than 30 days in wheat.

WSMV has been used as an expression vector to express TriMV cistrons in wheat to examine virus-virus interactions. The P1 protein of WSMV is a strong suppressor of RNA silencing. Consequently, even though many biotechnological applications are impaired by the host defense mechanism, WSMV P1 can be used to attain consistent high-level expression of transgenes in monocotyledonous plants. Additionally, transgenic plants expressing WSMV P1 can be used to enhance the levels of expression of viral vectors.

Concluding Remarks

Viral gene functions, viral proteins interacting with host and vector proteins, and mechanisms of suppression of host defense have been extensively studied for members of the genus *Potyvirus*. Among rymo- and tritimoviruses, extensive research has been performed particularly on WSMV regarding genetic diversity and the roles of HC-Pro and CP in vector transmission and disease development. However, knowledge of host and vector proteins required for disease development and transmission, respectively, is lacking. Knowledge of viral gene functions and interaction of viral proteins with host and vector factors could eventually facilitate the development of new management strategies. Identification of candidate host factors involved in disease development could be targeted via gene-editing technology to interrupt virus-host interactions. Ultimately, disruption of virus-host interactions could mitigate the viruses' ability to infect plants. This could be an important development especially for WSMV, the most important virus found in these two genera.

Nomenclature

aa	Amino acid(s)	nm	Nanometer
AlkB	Alpha-ketoglutarate-dependent dioxygenase	nt	Nucleotide(s)
CP	Coat protein	ORF	Open reading frame
dsRNA	Double stranded ribonucleic acid	OTu-Pro	Ovarian tumor-like protease
Hel	Helicase	Pol	RNA-dependent RNA polymerase
HTS	High-throughput sequencing	Poly(A)	Polyadenylated
IC-RT-PCR	Immunocapture reverse transcription polymerase chain reaction	P-Pro	Papain-like protease
kb	Kilobase	qRT-PCR	Quantitative reverse transcription polymerase chain reaction
kbp	Kilobase pair	RP	Replicase
kDa	Kilo Dalton	RT-PCR	Reverse transcription polymerase chain reaction
LAMP	Loop-mediated isothermal amplification	sgRNA	Sub-genomic RNA
ML	Maximum-likelihood	ssRNA	Single-stranded ribonucleic acid
MP	Movement protein	TGB	Triple gene block
Mtr	Methyl-transferase	V-region	Variable region

Glossary

Capillovirus	From Latin <i>capillus</i> (hair).	Prunevirus	From <i>Prunus</i> , genus name of the apricot (<i>Prunus armeniaca</i>), the natural host of the type species.
Chordovirus	From chord, the name of the strings on a harp or stringed instruments.	Tepovirus	From the type species <i>Potato virus T</i> .
Citivirus	From the type species <i>Citrus leaf blotch virus</i> .	Trichovirus	From Greek <i>thrix</i> (hair).
Divavirus	From the type species <i>Diuris virus</i> .	Trivirus	A virus member of the <i>Trivirinae</i> subfamily.
Fivivirus	From <i>Ficus</i> – <i>Vitis</i> , the genera name of the natural hosts of the type species in this newly proposed virus genus.	Vitivirus	From <i>Vitis</i> , generic name of the grapevine (<i>Vitis vinifera</i>) the host of the type species.
		Wamavirus	From the type species <i>Watermelon virus A</i> .

Introduction

The subfamily *Trivirinae* of the family *Betaflexiviridae* consists of viruses infecting predominantly woody plants such as fruit trees and grapevine but infection of herbaceous plants (in particular tuber crops) is also possible. Transmission of triviruses occurs through insect vectors, in particular pseudococcid mealybugs, aphids and erineum mites; transmission by grafting, seeds or mechanical means are also common. Triviruses are distributed worldwide; they often occur in mixed infections with other viruses (e.g., closteroviruses) so that it is difficult to correlate the symptomatology with the identity of the virus causing these symptoms. Triviruses have flexuous, non-enveloped particles (ranging in size from 640 to 1500 nm) that contain a positive-sense single-stranded RNA (ssRNA) molecule. The genome lengths range from approximately 6.45 to 8.75 kb. The name of the subfamily reflects the three conserved proteins that all members' genomes commonly encode, i.e., the replicase (RP), movement (MP) and coat proteins (CP). Currently, nine genera are recognized within the *Trivirinae* subfamily as well as thirty-eight assigned species although a range of newly proposed species is pending approval with constantly increasing numbers. Moreover, a new genus tentatively named "*Fivivirus*" was proposed recently.

Classification

Trivirinae is a subfamily within the family *Betaflexiviridae* (order: *Tymovirales*, realm: *Riboviria*). Nine genera are currently assigned to this subfamily i.e., *Capillovirus*, *Chordovirus*, *Citivirus*, *Divavirus*, *Prunevirus*, *Tepovirus*, *Trichovirus*, *Vitivirus*, and *Wamavirus*, with thirty-eight assigned virus species (Table 1). Several new members have been proposed recently, including Agave tequilana leaf virus (ATLV), Grapevine virus M (GVM) and Peach virus M (PeVM) (Table 1). Additionally, a new genus "*Fivivirus*" to include the tentative species i.e., Fig latent virus 1 (FLV1) and Grapevine Kizil Sapak virus (GKSV) was proposed recently. The name of the subfamily reflects the three conserved proteins that all members' genomes encode in common i.e., the RP, MP, and CP (Fig. 1). This distinguishes them from the members of the *Quinvirinae*, which have five conserved genes encoding the RP, triple gene block

Table 1 Overview of the genera assigned of the subfamily *Trivirinae* (*Betaflexiviridae*) including type species and biological properties (ICTV, 2019)

Genus	Particle size	Virus name	Acronym	Natural Hosts	Symptoms	Transmission	Distribution	Accession ^a
<i>Capillovirus</i>	670–700 × 12 nm	<i>Apple stem grooving virus^b</i>	ASGV	<i>Actinidia chinensis</i> , <i>A. deliciosa</i> , <i>Bambusa nana</i> , <i>Bauhinia variegata</i> , <i>Citrus</i> spp., <i>Cnidium officinale</i> , <i>Dendrocalamus dianxiensis</i> , <i>D. hamiltonii</i> , <i>Fargesia somnigensis</i> , <i>Ficus palmata</i> , <i>Malus</i> spp., <i>Nandina domestica</i> , <i>Phyllostachys pubescens</i> , <i>Prunus</i> spp., <i>Pyrus communis</i> , <i>P. pyrifolia</i> , <i>Rosa</i> spp. & <i>Rubus ellipticus</i>	Stem grooving/Graft Necrosis & Pitting/Tatter Leaf/Leaf Deformation/Chlorotic mottle/Leaf Epinasty	Graft- & seed-transmitted (lily, <i>Chenopodium quinoa</i>)	Worldwide in apple & citrus producing countries	NC001749

^aproposed genus.

^btype species.

^ctentative species.

^dit has been proposed to remove Fig latent virus 1 from the genus *Trichovirus* to the newly proposed genus *Fivivirus*.

Fig. 1 Graphical representation of the genomic organization of selective members of the family *Betaflexiviridae* showing the relative positions of the ORFs and their gene products. The motifs are Mtr: methyltransferase; OTu-Pro: ovarian tumor-like protease; AlkB: alpha-ketoglutarate-dependent dioxygenase; P-Pro: papain-like protease; Hel: helicase; Pol: RNA-dependent RNA polymerase; ?: cap structure has not been demonstrated yet. *Trivirinae*: ACLSV: Apple chlorotic leaf spot virus, ASGV: Apple stem grooving virus, AVCaV: Apricot vein clearing associated virus, CLBV: Citrus leaf blotch virus, DVA: Diuris virus A, GKSU: Grapevine Kizil Sapak virus, GVA: Grapevine virus A, LeCV1: Lettuce chordovirus 1, PVT: Potato virus T, WVA: Watermelon virus A. *Quinvirinae*: ASPV: Apple stem pitting virus, CNRMV: Cherry necrotic rusty mottle virus and RCMV: Red clover vein mosaic virus.

(TGB) and CP. The RP of triviruses belongs to the “alphavirus-like” supergroup of RNA viruses. The RP proteins are most closely related to those of other virus families in the order *Tymovirales* whereas the MPs of the “30K” superfamily are more closely related to those in the family *Virgaviridae*. For taxonomic assignment, host range, serological specificity, nt (less than 72%) or aa (less than 80%) identity of CP or RP as well as vector specificity have been used to distinguish species.

Virion Structure

The virions of triviruses are non-enveloped flexuous filaments with helical symmetry (with a pitch of approximately 3.3–3.8 nm). Depending on the negative contrast material used for electron microscopy, criss-cross or rope-like features can be visible. The virions are composed of a ssRNA molecule (representing approximately 5% of the virion weight) and a polypeptide (ranging in size from 18 to approximately 41 kDa). The length of the virions is genus-dependent and can vary from 640 to 1500 nm (Table 1) with a diameter ranging from 10 to 15 nm. Fig. 2 shows the virions of Potato virus T (PVT), a tepovirus. To maintain the integrity of the particles, divalent cations are required.

Fig. 2 Electron micrograph of Potato virus T (PVT; *Tepovirus*) particles. The micrograph shows non-enveloped flexuous filaments virions with helical symmetry. Courtesy: Katja R. Richert-Pöggeler, Julius Kühn Institute, Germany.

Genomic Organization and Properties of Encoded Proteins

The genomes of triviruses are encoded by a linear positive-sense ssRNA with two to five open reading frames (ORF) (**Fig. 1**). The 5' terminus has a 7-methyl-guanylate cap (m^7G) but this has not been confirmed for all genera. The 3' terminus is polyadenylated (poly(A)). The lengths range from approximately 6.45 to 8.75 kb excluding the poly(A) tail.

Genomes of triviruses have three conical genes encoding the RP, MP, and CP. ORF1 encodes the RP with a viral methyl-transferase (Mtr) motif at the N-terminal region, and viral helicase 1 (Hel) and RNA-dependent RNA polymerases (Pol) core motifs near the C-terminal region (**Fig. 1**). Additional motifs were reported in most members i.e., alpha-ketoglutarate-dependent dioxygenase (AlkB) and papain-like protease (*p*-Pro) motifs between the Mtr and Hel motifs. The ovarian tumor-like protease motif (OTu-Pro) could only be found on ORF1 of citriviruses (**Fig. 1**). A second ORF encodes a cell-to-cell MP of the "30K" superfamily (~ 31 to ~ 50 kDa). The third conserved ORF of triviruses encodes a CP of approximately 21–40.5 kDa.

The genomic organization of capilloviruses and divaviruses differs from the other genera in the subfamily *Trivirinae*. They have only two overlapping ORFs (**Fig. 1**). Their ORF1 encodes a polyprotein containing the RP and the CP. A "variable region (V-region)" can be found between the Pol motif (within the RP) and the CP where the aa sequence shows high variability among different virus isolates (**Fig. 1**). A second ORF, encoding the MP, is nested within the ORF1. An exception of capilloviruses is the recently identified Loquat virus A (LoVA). It possesses a genome composed of three ORFs, where the CP coding ORF3 is separated from the RP coding ORF1.

Chordoviruses, pruneviruses, vitiviruses, and some trichoviruses have, in addition to the RP, MP, and CP, a 3'-terminal ORF encoding a putative nucleic acid binding protein (NABP) with a zinc binding finger motif (approximately 10.2–17.1 kDa) (**Fig. 1**). Citriviruses, tepoviruses, and some trichoviruses have only the three conical genes. In vitiviruses, there is an additional ORF encoding a hypothetical protein (~ 17.2 to ~ 24.8 kDa) between the RP and the MP (**Fig. 1**). In wamaviruses, another ORF is located between the MP and the CP encoding a hypothetical protein of approximately 25 kDa.

The genome organization of the two putative members of the proposed genus *Fivivirus* FLV1 and GKSV are different. Four predicted, slightly overlapping ORFs were identified in the FLV1 genome, the putative RP, MP (43 kDa), CP (46 kDa), and NABP (12 kDa). GKSV has five predicted ORFs where the RP (196.7 kDa) is followed by the MP (31.7 kDa) which is slightly overlapped by the CP (22 kDa) and a hypothetical protein (21.4 kDa) is overlapped with a predicted NABP which overlap (11.7 kDa).

Phylogenetic Relationships of the Different Triviruses

Phylogenetic analysis based on RPs alignment of betaflexivirids shows that the triviruses of each genus are grouped together, mostly within well-supported branches (**Fig. 3(A)**). A slightly different picture emerges when using aa alignments of the MP: The MP of the citriviruses i.e., Citrus leaf blotch virus (CLBV) and Citrus leaf blotch virus 2 (CLBV2) form a group with pruneviruses. As triviruses have a "30K"-type MP while quinviruses have the TGB, quinviruses are not included in the tree. The closely related *Furovirus* genus (family: *Virgaviridae*) was used instead for the Maximum-likelihood (ML) tree (**Fig. 3(B)**). **Fig. 3(C)** shows an ML tree representing the phylogenetic relationship between the CP aa sequence of selective members of the subfamily *Trivirinae* and *Quinvirinae*. Interestingly, citriviruses and the wamavirus WVA are grouped with quinviruses (**Fig. 3(C)**).

Cellular Localization of Trivirus Particles and Viral Replication

Trivirus replication and assembly occur in the cytoplasm. Virions can be found in the cytoplasm of infected mesophyll, parenchyma, and phloem cells of leaves and roots. The cellular localization however is virus- and host-dependent. For example, virions of Grapevine virus A (GVA), Grapevine virus B (GVB) and Heracleum latent virus (HLV) (vitiviruses), and Apple chlorotic leaf spot virus (ACLSV; a trichovirus) are strictly phloem-limited, but in herbaceous hosts, they can be found in the parenchyma. Moreover, virions of ACLSV could be located in the nucleus. Trivirus particles accumulate in discrete bundles or paracrystalline aggregates in the cytoplasm where multiplication occurs. Trivirus-infected cells were found to be damaged to a varying extent. Some triviruses were found to cause tonoplast vesicular evagination where fine fibrillar material (suggested to be the replicative forms of the viral RNA) can be observed. Other cellular damages include enlarged starch grains, swollen chloroplasts and damaged mitochondria. Moreover, a study showed that ASGV infection of apple trees extensively alters the gene expression patterns even with no disease symptoms observed.

The expression of trivirus proteins relies on production of sub-genomic RNA (sgRNA) as suggested by the analyses of dsRNA patterns from infected plants. As an example, five dsRNA species were detected in plant tissues infected with apple stem grooving virus (ASGV; a capillovirus) i.e., 6.5, 5.5, 4.5, 2.0, and 1.0 kbp. The 6.5 kbp species represents the dsRNA of the full genome of ASGV. The 5.5 and 4.5 species are the 5' co-terminal with ASGV genomic RNA while the 2.0 and 1.0 kbp are suggested to be dsRNA of sgRNA of the MP and CP, respectively. Six dsRNAs species with sizes of about 7.5, 6.4, 5.4, 2.2, 1.1, and 1.0 kbp were detected in ACLSV-infected plant tissues. The largest dsRNA species here represent the full genome of the virus, the 6.4 and 5.4 dsRNA species are the 5' co-terminal with ACLSV genomic RNA. The dsRNA 2.2 and 1.1 kbp species are 3' co-terminal with ACLSV genomic RNA which could be representing the sgRNA of the MP and the CP, respectively. The 1.0 kbp species is internal to the genome.

It is suggested that the MP of triviruses acts as a suppressor of plant RNA silencing pathways. For example, ACLSV-MP suppresses the systemic movement of the silencing signal whereas CLB-V-MP suppresses the intracellular silencing without affecting the systemic spread of the signals.

Host Range and Distribution of Triviruses

Triviruses infect predominantly grapevine, citrus fruit and fruit trees/shrubs and therefore they can be found worldwide. The host range of triviruses appears to be quite narrow under natural conditions, infecting only one or few related plants species. However, under experimental conditions it is possible to transmit many triviruses mechanically to herbaceous indicator plants such as *Nicotiana* or *Chenopodium* spp. (see Table 1 for details on natural hosts). In recent years, many new triviruses have been described that infect herbaceous plants. For a long time, the tepovirus PVT (identified from potato crops in South America and classified in many countries as quarantine pest) and Heracleum latent virus (HLV) that was described from hogweed (*Heracleum sphondylium*)

Fig. 3 Maximum-likelihood (ML) trees of members of the subfamily *Trivirinae* (*Betaflexiviridae*) based on alignments of the amino acid sequences of (A) the replicase, (B) the movement, (C) the capsid proteins, and their homologs from representative members of subfamily *Quinvirinae* (*Betaflexiviridae*) and the genus *Furovirus* (*Virgaviridae*). MEGAX was used to perform MUSCLE alignments and for producing the ML trees (based on Jones-Taylor-Thornton (JTT) matrix-based model). The numbers on branches indicating the percentage of bootstraps (1000 bootstrap replications; only >50% are shown). The viruses and their accession numbers are: *Betaflexiviridae*: *Trivirinae*: *Capillovirus*: Apple stem grooving virus (ASGV; NC001749), Camellia ringspot associated virus 3 (CRSaV-3; MK050795), Cherry virus A (CVA; NC003689), Currant virus A (CuVA; NC029301), Loquat virus A (LoVA; MK936045), Mume virus A (MuVA; NC040568), Rubber tree virus 1 (RTV1; MN047299), Yacon virus A (YVA; NC030657), *Chordovirus*: Carrot Ch virus 1 (CtChV1; NC025469), Carrot Ch virus 2 (CtChV2; NC025468), *Citivirus*: Citrus leaf blotch virus (CLBV; NC003877), Citrus leaf blotch virus 2 (CLBV2; MH144344), *Divavirus*: Diuris virus A (DVA; NC019029), Diuris virus B (DVB; NC019030), Hardenbergia virus A (HarVA; NC015395), Ocimum basilicum RNA virus 1 (ObRV1; NC035462), *Fivirus* (*proposed genus): Grapevine Kizil Sapak virus (GKSV; MN172165), *Prunavirus*: Apricot vein clearing associated virus (AVCaV; NC023295), Camellia ringspot associated virus 1 (CRSaV-1; MK050792), Camellia ringspot associated virus 2 (CRSaV2; MK050793), Caucasus prunus virus (CPrV; NC038325), *Tepovirus*: Potato virus T (PVT; NC011062), Prunus virus T (PrVT; NC024686), *Trichovirus*: Apple chlorotic leaf spot virus (ACLSV; NC001409), Apricot pseudo-chlorotic leaf spot virus (APsCLSV; NC006946), Cherry mottle leaf virus (CMLV; NC002500), Grapevine berry inner necrosis virus (GINV; NC015220), Grapevine Pinot gris virus (GPGV; NC015782), Peach mosaic virus (PcMV; NC011552), Peach virus M (PeVM; MK012336), *Vitivirus*: Actinidia virus A (AcVA; LC491285), Actinidia virus B (AcVB; NC016404), Agave tequilana leaf virus (ATLV; NC034833), Arracacha virus V (AVV; NC034264), Blackberry virus A (BVA; NC040630), Blueberry green mosaic associated virus (BGMAV; MK460433), Grapevine virus A (GVA; NC003604), Grapevine virus B (GVB; NC003602), Grapevine virus D (GVD; MF774336), Grapevine virus E (GVE; NC011106), Grapevine virus F (GVF; NC018458), Grapevine virus G (GVG; NC040554), Grapevine virus H (GVH; NC040545), Grapevine virus I (GVI; NC037058), Grapevine virus J (GVJ; NC040564), Grapevine virus K (GVK; NC035202), Grapevine virus M (GVM; MK492703), Heracleum latent virus (HLV; MN314973), *Wamavirus*: Watermelon virus A (WVA; NC034377). *Betaflexiviridae*: *Quinvirinae*: *Carlavirus*: Potato virus M (PVM; NC001361), Hop latent virus (HpLV; NC002552), Garlic latent virus (GLV; NC003557), Red clover vein mosaic virus (RCVMV; NC012210), *Foveavirus*: Apple stem pitting virus (ASPV; NC003462), Peach chlorotic mottle virus (PCMV; NC009892), Apricot latent virus (ApLV; NC014821), Apple green crinkle associated virus (AGCaV; NC018714), *Robigovirus*: Cherry green ring mottle virus (CGRMV; NC001946), Cherry necrotic rusty mottle virus (CNRMV; NC002468), African oil palm ringspot virus (AOPRV; NC012519), Cherry rusty mottle associated virus (CRMaV; NC020996). *Virgaviridae*: *Furovirus*: Oat golden stripe virus (OGSV; NC002358), Chinese wheat mosaic virus (CWMV; NC002359), Sorghum chlorotic spot virus (SrCSV; NC004014), Japanese soil-borne wheat mosaic virus (JSBWMV; NC038850).

in Europe were the only triviruses found naturally on herbaceous plants. New triviruses found on non-woody plants include Yacon virus A (YVA; a capillovirus) that infects tuberous plants (*Smallanthus sonchifolius*); Carrot chordovirus 1 and 2 (CtChV1 and CtChV2) as well as Lettuce chordovirus 1 (LeCV1; *Chordovirus*) that were identified from carrots (in the UK) and lettuce (from France), respectively; Diuris virus A and B (DVA and DVB) from donkey orchids (*Diuris penduculata*) and Hardenbergia virus A (HVA; *Divavirus*) from the legume *Hardenbergia comptoniana*, from Australia; Zosteria virus T (ZVT; *Tepovirus*) that infects *Zostera muelleri*, a seagrass species that can be found in regions of Australia, New Zealand, and Papua New Guinea; Phlomis mottle virus (PhMV; *Trichovirus*) infecting *Phlomis* spp. in the Mediterranean region; Agave tequilana leaf virus (ATLV; *Vitivirus*) infecting *Agave tequilana* in Mexico, Arracacha virus V (AVV) and Arracacha latent virus (ALVV; *Vitivirus*) infecting the South American root crop *Arracacia xanthorrhiza*; Mint virus 2 (MV2; *Vitivirus*) from mint in USA and Watermelon virus A (WVA) infecting watermelon (*Citrullus lanatus*) in China. Recently discovered triviruses include also LoVA from loquat (*Eriobotrya japonica*) in China, Rubber tree virus 1 (RTV1; *Capillovirus*) infecting rubber trees (*Hevea brasiliensis*) in China, Camellia ringspot associated virus 1, 2 and 3 (CRSaV1, CRSaV2; *Prunivirus*, and CRSaV3; *Capillovirus*) from *Camellia* spp. in the USA, and Blueberry green mosaic-associated virus" (BGMaV; *Vitivirus*) from blueberries in the USA. Only limited information is available on alternative hosts or distribution of these viruses in other regions.

Symptomology, Impact and Vectors

Common symptoms in fruit trees include graft incompatibilities, necrosis and pitting of the graft union and stem grooving of wood; leaf symptoms may include chlorotic spots, line patterns or ring spots, mottling, mosaic or necrotic spots (Fig. 4). For example, ACLSV causes symptoms like bark split and dark green sunken mottle (Fig. 4(A) and (B)), AVCaV causes symptoms of

Fig. 4 Symptoms induced by triviruses. (A) Symptoms of bark split caused by Apple chlorotic leaf spot virus (ACLSV) in plum (cv. Prune d'Ente), (B) Typical dark green sunken mottle caused by an ACLSV isolates in the GF305 peach seedling indicator, (C) Symptoms of vein clearing and blotching observed on apricot leaf infected with Apricot vein clearing-associated virus (AVCaV), (D) *Vitis berlandieri* × *V. riparia* (indicator plants) expressed stem grooving disease associated with infection by Grapevine virus A (GVA); Bottom is healthy control, (E) Couderc 1613 × *V. berlandieri* (indicator plants), developed corky-bark symptoms associated with infection by Grapevine virus B (GVB); Bottom is healthy control. Courtesy: (A) Jean Dunez, INRAE, France, (B) Thierry Candresse, INRAE, France, (C) Toufic Elbeaino, Istituto Agronomico Mediterraneo di Bari, Italy, (D) and (E) Maher Al Rwahnih, Foundation plant Services – University of California – Davis, USA.

vein clearing and blotching on apricot leaves (Fig. 4(C)), and color breaking of petals was observed for PcMV infection. Fruits may be smaller, ripen late or may have wart-like outgrowths or injuries. The majority of grapevine-infecting triviruses does not cause visible symptoms on the plants; some infections may lead to necrotic spots, mosaic, mottle or ring spots on leaf but more dramatic is the effect on yield quantity and quality e.g., of Grapevine Pinot gris virus (GPGV) on berry quantity and quality that may be both reduced in these economically important crops. As another example, GVA is associated with pitting and grooving of wood but occurs very often in mixed infections with other viruses (Fig. 4(D)); corky bark disorder was described for GVB infection (Fig. 4(E)) whereas Grapevine virus D (GVD) is associated with corky rugose wood disease. Both GVA and GVB are associated with the Kober stem grooving syndrome.

However, for many triviruses, no specific symptoms were observed, e.g., HLV may cause no symptoms at all. Many of the recently added triviruses were identified during virus ecology studies using high-throughput sequencing technologies (HTS) of pooled samples and therefore symptoms cannot be attributed to the identified viruses. Mixed infections of triviruses and in particular with closteroviruses (family: *Closteroviridae*) are quite common in nature; multiple infections of one plant with several triviruses have also been reported. An example is the occurrence of Grapevine leafroll-associated viruses (GLRaVs; closteroviruses) and the vitiviruses GVA, GVB, GVD, GVE, and GVF in mixed infections of vineyards. As another example, the Plum bark necrosis stem pitting-associated virus (PBNPaV, *Closterovirus*) and Apricot vein clearing associated virus (AVCaV, *Prunivirus*) can be found in dual/mixed infections. Therefore, it is difficult to assign a certain symptomology to infection with a specific virus.

Most, if not all, fruit tree- and grapevine-infecting triviruses are graft-transmissible; many triviruses could be transferred mechanically under experimental conditions to herbaceous indicator plants. Transmission via seeds was reported in few studies e.g., PVT, CRSaV1, CRSaV2, CRSaV3, and ASGV (for ASGV, seed-transmission was shown only for indicator plants e.g., lily and *Malus platycarpa*, but it is unclear if this dissemination route is of major importance under natural conditions). Insect vectors appear to have a more prominent role in transmission of triviruses; HLV and Mint virus 2 (MV2) can be transmitted by aphids; fruit tree and grapevine-infecting triviruses can be transmitted by eriophyid mites (*Eriophyes inaequalis*: transmitting CMLV; *Eriophyes insidiosus*: transmitting PcMV), erineum mites (*Colomerus vitis*: transmitting GINV and GPGV) and various mealybug species (*Pseudococcus longispinus*, *Ps. affinis*, *Planococcus ficus*, *Pl. citri*, *Phenacoccus aceris*) and scale insects (*Neopulvinaria innumerabilis*) that are involved in the transmission of GVA, predominantly. It appears that L1 stages of *Ph. aceris* are more efficient vectors than L2, L3 or adult females although the reasons are unknown. They are transmitted in semi-persistent manner. Moreover, HLV was found to require Heracleum virus 6 (HV6; synonym of Carrot yellow leaf virus [CYLV], a closterovirus) as a helper for vector transmission. For many of the novel triviruses, information on vectors or alternative routes of transmission is missing (Table 1).

Diagnosis

Many of the early investigations on triviruses used test plants as bioassays for induction of symptoms and propagation of viruses. However, these bioassays cannot be used for identification and characterization of triviruses and are laborious. It is possible to identify virions by various electron microscopy techniques, i.e., transmission electron microscopy, immunogold labeling, or immunosorbent electron microscopy. Depending on the genus, trivirus virions are poor to moderate antigens. Several polyclonal antisera and monoclonal antibodies have been developed for the detection and identification of several triviruses. Cross-reaction of antibodies can occur; e.g., antibodies raised against CMLV cross-react with PcMV. Other monoclonal antibodies have been produced for the specific identification of GVD; those antibodies did not cross-react with other vitiviruses.

Various PCR-based assays have been developed for the sensitive and reliable detection of triviruses. Depending on primer design, these assays were successfully implemented to detect specifically individual viral species but the use of degenerate primers such as dPR1 and dPR2 allowed the detection of several vitiviruses (GVA, GVB, GVD, HLV), a tepovirus (PVT) and a divergent ACLSV isolate (*Trichovirus*).

Improved sensitivity compared to a conventional RT-PCR assay was achieved using an immunocapture RT-PCR (IC-RT-PCR) assay for the detection of ASGV. In this assay, polyclonal antibodies were used to trap the virus particles followed by RT-PCR using ASGV specific primers. However, these assays have mainly been replaced with multiplex assays targeting multiple viruses and/or quantitative RT-PCR (qRT-PCR) protocols.

As many triviruses are present in mixed infections, several multiplex detection assays have been developed, in particular for grapevine and fruit trees. For example, multiplex RT-PCR and qRT-PCR assays were designed for the simultaneous detection of several grapevine viruses including GVA and GVB. For a Canadian survey of grapevines, a multiplex RT-PCR assay targeting seventeen grapevine viruses (including GVA, GVB, GPGV) was generated and successfully applied in the detection of the triviruses in the Ontario region. For fruit trees, RT-PCR protocols for the simultaneous detection and identification of eight stone fruit viruses (including ACLSV), four cherry viruses (including CVA), and pear viruses (including ASGV or ACLSV) have been reported.

A single qRT-PCR assay for simultaneous detection of GVA, GVB, and GVD was more sensitive and faster than a conventional RT-PCR assay that used degenerate primers to detect these viruses. Similar qRT-PCR protocols were for example developed for the detection of citrus viruses such as Citrus tristeza virus (*Closteroviridae*), Citrus psorosis virus (genus *Ophiovirus*, family *Aspiviridae*) and CLBV or the detection of ASGV, Apple stem pitting virus (*Foveavirus*) and Apple mosaic virus (*Ilarvirus*).

Recently, loop-mediated isothermal amplification (LAMP) assays have also been established for fast and sensitive detection of triviruses and have been applied for the detection of ACLSV.

The biggest challenge, however, for the development of specific and sensitive detection assays lies in the development of HTS technologies and the subsequent description of novel virus species and divergent isolates of known viruses. Many new triviruses have been detected recently using HTS (e.g., Grapevine virus M (GVM), WVA, AVCaV, etc.); diagnostic assays need to either be adapted to reflect the detection of these new species or have to be developed from scratch.

Prevention and Treatment

Grapevine and fruit trees, the major host groups of viruses belonging to the *Trivirinae*, are crops of high economic value. They are also perennial plants, and often the highest yield or quality of fruits is only achieved after a few years of planting. The effect of infection with triviruses on these crops may not only be seen in quantitative yield reduction but also in qualitative damage to fruits or secondary metabolites influencing, e.g., the fruit aroma. Most of the preventative and curative measurements apply generally to viruses and viroids. Foremost, preventative measures such as quarantine programs and certification schemes have been adapted to provide healthy root stocks and bud wood as well as other planting material. Rules and recommendations for the provision of “virus-free” material are set by numerous organizations and networks world-wide for grapevine, stone and citrus fruits (e.g., International Council for the Study of Virus and Virus-like Disease of the Grapevine (ICVG), National Clean Plant Network (NCPN), Canadian Plant Protection Export Certification Program (PPECP), Commission of the European Union, North American Plant Protection Organization (NAPPO), European and Mediterranean Plant Protection Organization (EPPO), etc.). However, correct identification of (latent) infection is often hampered by the lack of sensitive detection methods or the presence of unknown viruses or divergent isolates for which a specific test has not been developed yet. Nevertheless, the prophylactic measures can provide healthy propagation material including seeds from which new orchards/vineyards can be planted.

Eradication of infected plants might be successful if detected early and limited to a small geographic region. Secondary spread of the disease may be slowed down but in practice, it has been difficult to eradicate the pathogens completely, in particular if vectored by (fast moving) insects. Vector control using insecticides has become increasingly difficult to apply due to the detrimental effects on non-target organisms and the environment, and the development of insecticide-resistant vectors themselves. Additionally, in certain areas of the world there is a political desire to reduce the use of synthetic pesticides. Biological antagonists (such as predatory insects) of trivirus vectors (mites, mealy bugs and scale insects) are poorly studied, especially under field conditions. This knowledge gap whether antagonists can reduce vector populations thus reducing virus transmission needs to be closed in the future.

Only few curative measurements for virus elimination of plant material have been described. Some of these have been successfully applied to eradicate trivirus infection; in particular, elimination of GVA seems to be quite successful. These methods include thermotherapy, meristem tip/shoot tip cultures, somatic embryogenesis, chemotherapy (using ombuin, glycyrrhizin/quercetin, ribavirin, and quercetin/ribavirin), and electrotherapy, applied either alone or in combination. However, these methods may induce undesired by-effects such as phytotoxicity, putative mutagenic effects and the induction of somaclonal variation.

To date, no natural resistance against triviruses has been described. Transgenic approaches showed some limited effects in the control of triviruses: In model plants (such as *N. benthamiana*) reduction of virus titer and absence of virus symptoms was observed in plants expressing GVA-CP or GVA/GVB-MPs. *N. benthamiana* plants expressing a GVA mini-replicon were extremely resistant to GVA infection but susceptible to GVB. Interestingly, *N. occidentalis* plants that were expressing ACLSV-CP were resistant to GINV infection but not to ASGV or ASPV infection. Furthermore, partially functional deletion mutants of ACLSV also conferred resistance to GINV, probably due to interference with viral long-distance movement. An artificial microRNA derived from grapevine was engineered to target GVA genomic sequences in *N. benthamiana* thus inducing various degrees of resistance in that host.

Although it was possible to transform grapevine embryonic tissue with MP genes from GVA or GVB, the resulting plants showed phenotypic abnormalities. Attempts to use the CP genes from GVA or GVB for transformation grapevine seems to be not successful. It therefore seems that due to practical and political reasons, virus-resistance introduced by transgenic approaches is currently not a short-term option.

Glossary

Icosahedron A solid having 20 faces and 12 vertices.

Phylogeny The complete evolutionary history of group of animals, plants, bacteria, viruses, etc.

Pseudoknot RNA structure formed by base-pairing between nucleotides within the loop subtending a stem and nucleotides outside of this loop.

Sub-genomic RNA Derived from a viral RNA genome during replication, serves as mRNA for the expression of genes that are translationally silent in the genomic RNA.

The Family and Its Distinguishing Features

The members of the family *Tymoviridae*, in the order *Tymovirales*, are presented in [Table 1](#). Like the family itself, the genus *Tymovirus* derives its name from the type species, *Turnip yellow mosaic virus*. Turnip yellow mosaic virus (TYMV) was first isolated in 1946 and is by far the most intensively studied member of the family. Indeed, TYMV is one of the best-characterized plant viruses. The family was created in recognition of the close relationships between the genera *Tymovirus*, *Marafivirus*, and the founding member of newly created genus *Maculavirus*, Grapevine fleck virus (GFkV). Poinsettia mosaic virus (PnMV) and Bombyx mori latent virus (BmLV) are currently family members unassigned to a genus. Complete genome sequences are available for the type species of each of the three genera of the *Tymoviridae* and for PnMV and BmLV. Newly described tentative tymoviruses having sequence homologies and similar genome expression strategies, but not yet assigned to the family are listed at the end of [Table 1](#).

The members of the family *Tymoviridae* are characterized by their icosahedral, non-enveloped, ~29 nm virions, that can readily be visualized by negative-staining electron microscopy (EM). Infections produce a characteristic mixture of filled, infectious virions, and empty or near-empty capsids. Regular surface features, representing prominent peaks formed by pentamers and hexamers of coat protein (CP) molecules, are evident by EM and by molecular structure and computer rendering ([Fig. 1](#)).

The genomes of members of the *Tymoviridae* are composed of a single positive ssRNA generally 6.0–6.5 kb long, although the genome of GFkV is 7.5 kb long. Sub-genomic RNAs of 1 kb or less are associated with CP expression. All *Tymoviridae* genomes have a distinctive skewed nt composition that is rich in C residues (32%–50%). The unifying characteristic of the genome design of all *Tymoviridae* members is the presence of a long open reading frame (ORF) that covers most of the genome and encodes the replication polyprotein with identifiable domains: methyl-transferase, papain-like proteinase, helicase, and RNA-dependent RNA polymerase (RdRp) in order N- to C-terminal ([Fig. 2](#)). The CP ORF is situated downstream of the polyprotein ORF, to which it is fused in the marafivirus and PnMV genomes. Close familial relationships are easily discerned from alignments of the sequences of the RdRp and CP genes.

Most viruses in the family have narrow host ranges. Many of the tymoviruses have been isolated from non-crop hosts and have thus far not presented major disease threats to crops. Marafiviruses are associated with significant crop losses, perhaps resulting from their more effective transmission by flying insects. Disease symptoms include bright yellow mosaic or mottling (tymoviruses and PnMV), chlorotic stripes, vein clearing, etched lines or dwarfing (marafiviruses), and leaf flecking (maculaviruses).

Table 1 Members of the family Tymoviridae

Species name	Virus acronym	Complete sequence accession no.
<i>Genus Tymovirus</i>		
<i>Anagyris vein yellowing virus</i>	AVYV	AY75180
<i>Andean potato latent virus</i>	APLV	JX508291
<i>Andean potato mild mosaic virus</i>	APMMV	JX508290
<i>Belladonna mottle virus</i>	BeMV

Fig. 1 Tymovirus particle structure. Rendering of a tymovirus particle based on experimental data deposited in the ViperDB database is shown on the left. The different colors denote the distance from the center of the virus, the brighter regions being more distant. Molecular structure courtesy of Antonio Šiber, available at: http://www.antoniosiber.org/publikacije_en.html. A negative-contrast electron micrograph of virions and 'empty' particles of belladonna mosaic tymovirus is shown at right, with the high-magnification inset showing the prominent surface structure. Scale = 100 nm. Image courtesy Dr. D.-E. Lesemann.

Fig. 2 Genomes of the type members of the genera of the family *Tymoviridae* and of PnMV. All genomes have a 5'-m7GpppG cap, but the 3' terminal structures vary. TYMV has a valine-specific tRNA-like structure (cloverleaf), MRFV, GFKV and PnMV have a poly(A) tail. The known or predicted (?) expressed ORFs are indicated with the molecular weight (K, kDa) of the predicted protein. The replicases (RPs) all possess methyltransferase (Mtr), papain-like proteinase (Pro), helicase (Hel), and RdRp domains. The TYMV RP is cleaved as indicated, and similar cleavages are expected for the other viruses. The TYMV overlapping protein (OP) is the viral movement/RNAi suppressor protein. The TYMV CP is expressed from a sgRNA, and all other CPs are probably also expressed from sgRNAs (not shown). The 28 kDa MRFV CP (whose true size is likely to be closer to 25 kDa) may be produced by proteolytic cleavage from the RP-CP fusion protein, and an analogous event may occur with PnMV. Expression of the MRFV p43 and GFKV p31 and p16 has not yet been validated.

Tymoviruses

Properties and Distinguishing Characteristics

Although virtually all information about tymoviruses has been derived from studies on TYMV, it is considered to be generally applicable to the other members of the genus. Virions of tymoviruses contain genomic RNAs 6.0–6.7 kb long and produce a single 3′ colinear sgRNA less than 1 kb in length encoding the ~20 kDa CP. Their genomes include a distinctive 16-nt-long ‘tymobox’ sequence, and the genomes of most species possess a 3′ tRNA-like structure (TLS) that can be efficiently esterified with valine. The genomes encode three ORFs (Fig. 2), two of which almost completely overlap: the OP and RP ORFs, which begin at AUG codons separated by only 4 nt. Tymoviruses replicate in all major tissues of their host plants, and accumulate to high levels (more than 0.1 mg g⁻¹ leaf tissue). Both filled and empty or near-empty particles accumulate. They are readily transmitted mechanically under laboratory conditions, and are spread over limited distances by beetle vectors in nature. Infection produces mosaic symptoms and a distinctive cytopathy that is evident upon EM observation by the appearance of small vesicles on the surface of chloroplasts, together with vacuolation and clumping of chloroplasts.

Capsid Structure

Virions of tymoviruses are highly stable ~29 nm, *T*=3 icosahedra formed by 180 copies of the single CP, arranged as 12 pentamers and 20 hexamers. These groupings form the vertices with fivefold and sixfold symmetry that constitute the surface peaks visible upon high-resolution EM observation (Fig. 1). Inter-subunit stabilization is provided primarily by hydrophobic protein–protein contacts, allowing the formation of stable shells that appear to be devoid of RNA. These empty or near-empty capsids can account for about one-third of the particles present in infected tissues and are readily identifiable by internal staining in negative-contrast EM (Fig. 1). They sediment as the ‘top component’ at 45–55S in CsCl density gradients, and readily separate from the ‘bottom component’, the infectious 110–120S virions that contain the genomic RNA. Minor components of intermediate density contain a range of sub-genomic-size RNAs that can be translated to yield CP. Roughly equimolar amounts of genomic and sgRNAs are encapsidated, but the precise disposition of sgRNA in the various particles has not been determined. Like many other viral CPs, tymoviral CPs fold into eight-stranded, β -barrel, jelly-roll structures. However, unlike some other CPs, there is no positively charged domain at the N-terminus for interaction with RNA and charge neutralization during packaging. Charge neutralization is thought to be provided by polyamine molecules (mostly spermidine) associated with the RNA. The crystal structures of empty and infectious particles have been determined for TYMV, Desmodium yellow mottle virus (DYMV), and Physalis mottle virus. Consistent with the dominance of protein–protein interactions in particle stabilization, empty and infectious particles have very similar structures.

Packaging signals in tymoviral RNAs have yet to be identified, though RNA recruitment may involve conserved hairpins in the 5′ untranslated region (UTR) and interaction of C-rich segments of the RNA with CP at low pH. Localized areas of low pH (5–6) have been postulated to arise at the surfaces of photosynthesizing chloroplasts. Tymoviral replication occurs in characteristic vesicles that form at the chloroplast surfaces (see below), and capsid formation is most active near these vesicles, suggesting a possible coupling between replication and encapsidation during infection. Despite much effort, there has been no success in developing a cell-free packaging system. These efforts have focused on the possible role of ‘artificial top component’ (ATC) capsids as decapsidation and encapsidation intermediates. ATCs are protein shells devoid of RNA that can be made from infectious virions by treatments such as freeze–thawing and exposure to high pH and pressure. They are similar in structure to infectious virions, but lack a capsomere of six CP molecules that is ejected during the treatment, allowing RNA escape.

Genome Organization

Tymoviral genomic RNAs possess a 5′ m⁷GpppG cap and terminate at the 3′ end in -CC(A) except for Dulcamara mottle virus (DuMV) that is in most cases part of a TLS. The typical tymoviral TLS is just over 80 nt long, has a distinctive pseudoknot close to the 3′ terminus, and is a close structural mimic of cellular tRNA^{Val}. A valine-specific anticodon is present, and the 3′ terminus can be specifically amino-acylated with valine. The valylated RNAs of some, though not all tymoviruses, can form a tight complex in vitro with the GTP-bound form of translation elongation factor eEF1A. Most molecules of encapsidated RNA lack the terminal A residue in the -CC(A) end, which is thought to be added by the host tRNA-specific CCA-nucleotidyl-transferase at the beginning of infection. The main roles of the TYMV TLS are thought to be (1) as a 3′ enhancer of translation initiation, (2) as a regulator of the onset of RNA replication by modulating access by the polymerase to the 3′ end, and (3) in maintaining an intact-CCA 3′ end. A minority of tymoviral genomic RNAs have 3′ UTRs that lack the typical valine-specific TLS (DuMV, Erysimum latent virus, and Nemesia ring necrosis virus, NeRNV).

Tymoviral RNAs act as cap-dependent messenger RNAs. Of the three ORFs, two (OP and RP) are expressed directly from the genomic RNA, whereas the third (CP) is expressed from the 5′ capped sgRNA (Fig. 2). Although the sequence contexts around the OP and RP initiation codons vary, 4 nt always separates these closely spaced AUGs. The RP ORF covers most of the viral genome, and encodes the ~200 kDa RP, the only viral protein essential for supporting viral RNA replication in protoplasts. This ORF encodes discrete domains (Fig. 2) that are discernable by sequence relationships to similar domains encoded by a wide

variety of positive-stranded RNA viral genomes. Particularly the RdRp domain is well conserved and appropriate for phylogenetic comparisons. Closely related, yet distinct, tymoviral genomes have RdRp domains with about 70% nt sequence identity. The RP is translated as a precursor protein that subsequently undergoes maturation cleavage catalyzed by the papain-like proteinase domain. The single known cleavage separates the RdRp domain from the remainder of the RP; thus, for TYMV, the precursor p206 is processed to yield p141 and p66.

The OP ORF almost entirely overlaps the RP ORF. Its length and the sequence of the encoded protein are highly variable. OPs range between 49 and 82 kDa, and have only 25%–40% aa sequence identity between the most closely related pairs of viruses. OP expression is needed for establishment of infection and for spread of the virus in plants. The OP is a suppressor of the host RNA silencing antiviral response and is also believed to be the viral movement protein. It is a substrate for ubiquitin-dependent degradation by the proteasome. Long-distance movement of the virus in plants requires expression of the CP. The CP ORF initiates close to the end of the RP ORF, sometimes even a little upstream. CP sequences are variably conserved among tymoviruses, with 36%–86% aa sequence identity between the most closely related pairs of viruses.

Tymoviral genomes possess a highly conserved sequence, the 16 nt tymobox (–GAGUCUGAAUUGCUUC) with small variations in some viruses, especially wild Cucumber mosaic virus, just upstream of the CP ORF. The tymobox and its associated ‘initiation box’ sequence CAA(U/G) positioned 8 or 9 nt downstream of the tymobox are believed to serve as the core elements of the sgRNA promoter. The tymobox overlaps with the 3′ end of the RP ORF, resulting in the presence of the tripeptide – ELL – near the C terminus of all RPs.

Replication Cycle

The ultrastructural changes that reflect viral replication activity and that result in the distinctive pathology of the chloroplasts have been particularly well described for TYMV. As is typical of positive-stranded RNA viruses, the replication cycle is completed entirely in the cytoplasm, and RNA replication occurs in association with membranes, specifically the chloroplast outer membrane. Vesicles 50–80 nm in diameter form as invaginations of the two outer membranes of chloroplasts. They form before the appearance of virions, which are initially found close to vesicle clusters and later throughout the cytoplasm; in some cases, empty capsids accumulate in nuclei. The RdRp has been localized to zones on chloroplasts that are rich in vesicles, and this localization depends on protein–protein interaction between the proteinase and RdRp domains of the mature RPs p141 and p66, respectively.

RNA replication occurs via the production of full-length minus strands, whose synthesis in TYMV is directed by the 3′ terminal –CCA serving as promoter and initiation site. No other minus-strand promoter elements have been identified in the 3′ UTR. As mentioned above, the tymobox appears to function with the initiation box as the core of the promoter directing sgRNA synthesis by internal initiation on the minus strand. The sgRNA of TYMV has a m7GpppA 5′ terminus.

Studies on the functions of viral proteins and of cis-acting sequences in the genomic RNA have been greatly facilitated by the use of ‘infectious clones’, that is, molecularly cloned cDNA versions of the genome from which infectious RNA can be derived.

Infection and Transmission

Tymoviruses cause chlorotic mosaic, vein-clearing, and mottling symptoms, generally without strong stunting. Host ranges are mostly narrow, and to date, no tymoviruses infecting monocot plants have been isolated. Tymoviruses are transmitted over limited distances by chrysomelid beetles, and some are weakly seed-transmissible. Tymoviruses and PnMV are readily transmitted mechanically and accumulate to high titers in infected plants.

Phylogenetic Relationships and Species Demarcation

In the past, serology using antisera raised against intact virus was the main criterion in classifying tymoviruses and in distinguishing between species. This is no longer the most convenient approach, however, and it has in fact been shown that distinct viruses whose genomic and CP sequences have identities less than 80% and 90%, respectively, can appear to be serologically identical. This seems to be due to similar or identical dominant epitopes within otherwise distinct CPs.

The study of relationships among tymoviruses and to other viruses currently primarily relies on the interpretation of sequences derived from the genomic RNA. The phylogenetic trees based on the sequences of the CP and the RP (**Fig. 3**) show similar relationships, both among the tymoviruses and to the other members of the family *Tymoviridae*. Genomes of the *Tymoviridae* are not under positive selection and recombination might be the major driving force of diversity within the family. For instance, the genome of NeRV, which has a tobamovirus-type TLS capable of amino-acylation with histidine, indicates that recombination can occur and shape tymoviral genome evolution. Also, family-wide recombination analysis showed that *Physalis* mottle virus can be a donor for other marafivirus members. The complete genome sequences are available for 35 tymoviruses or tentative tymoviruses (**Table 1**).

Alignments based on the replicase protein sequences indicate that the capilloviruses, carlaviruses, trichoviruses, and potexviruses, all members of the *Flexiviridae*, are the next most closely related virus groups. More distant sequence relationships indicate that members of the family *Tymoviridae* belong to the alpha-like virus group in the *Tymovirales*, the newly established order of viruses reported by the International Committee on Taxonomy of Viruses.

Fig. 3 Maximum-likelihood phylogenetic trees showing the relationships between members of the family *Tymoviridae* based on amino acid sequence alignments of (a) RdRp and (b) coat protein (CP) sequences. Bootstrap support values (%) above 70% are indicated at supported nodes. Branch lengths reflect the difference between amino acid sequences. Viruses from each of the three genera are separately shaded as marked. Viruses with tentative taxonomic status are marked with an asterisk.

Marafiviruses

Properties and Distinguishing Characteristics

Three current members of the genus *Marafivirus* are viruses principally infect monocots (grasses), while others infect citrus, tree fruits, grapevine, and blackberry. Another tentative two marafiviruses were isolated from grapevine. Plant host ranges are narrow. The genomes are 6.3–6.8 kb long, with a single ORF encoding an RP/CP fusion protein covering most of the genome. Two forms of the same CP (~25 and ~21 kDa) are found in virions. A single 3'-colinear sgRNA (< 1 kb) encoding the smaller form of the CP is produced during infection. A slightly modified form of the tymobox sequence, termed 'marafibox', is present in the genome near the junction between the RdRp- and capsid-coding sequences. Marafiviruses are phloem-limited and not mechanically transmissible. The grass-infecting marafiviruses are transmitted by cicadellid leafhoppers in a persistent-propagative manner, involving virus replication in the insect.

A distinctive feature of the marafiviruses is the presence of two CPs in the virions, a major CP ~21 kDa form and a minor N-terminally extended 22–28 kDa form. The latter is thought to arise by proteolytic release from the polypeptide, whereas the former is expressed from the sgRNA. The production of this sgRNA is probably under the control of the marafibox, a 16 nt sequence (–CA(A/G)GGUGAAUUGCUUC–) very closely related to the tymobox, and the –CA(A/U)-initiation box located 8 nt downstream. The roles of the two forms of CP are unclear.

Virion Structure, Genome Organization, Replication Cycle, and Phylogenetic Relationships

Marafiviruses produce virions and empty capsids that are similar to those produced by tymoviruses when observed by negative-staining EM. However, due to the phloem-limited replication of marafiviruses, the yield of virus is low, limiting the usefulness of EM for viral identification. Complete genome sequences are available for eight confirmed marafiviruses (Table 1).

Marafivirus genomic RNAs appear to be 5' capped but they lack the 3' TLS that is distinctive of tymoviruses, and marafivirus genomes possess a 3' poly(A) tail. Almost the entire genome of marafiviruses is devoted to encoding a large 224–240 kDa polypeptide, which includes replication-associated and CP domains (Fig. 2). The relationships between the CP and RP genes of the marafiviruses and other members of the family *Tymoviridae* are indicated in Fig. 3. The polypeptide is believed to be proteolytically processed by the viral proteinase at two sites, between the helicase and RdRp domains as in tymoviruses, and between the RdRp and CP domains. Polypeptide cleavage sites were experimentally mapped in TYMV and OBDV, and aa sequence alignments have

discerned probable cleavage sites occurring immediately downstream of Gly-Gly or Gly-Ala dipeptides at the helicase–RdRp and RdRp–CP junctions in marafivirus polyproteins.

As the number of complete marafivirus genome sequences increases, the taxonomic implications of evident variation in genome organization may be clarified. MRFV possesses a predicted significant overlapping ORF, encoding a putative 43 kDa protein, while Grapevine syrah virus 1 has a predicted 26 kDa protein that shares 43% identity with the central portion of the 43 kDa of MRFV; expression *in vivo* has not been verified for either protein. Related but strongly interrupted coding sequences have been identified overlapping the methyl-transferase domains of other marafiviral genomes and, based on sequence similarities to tymoviral OP, it has been postulated that these sequences represent variously degenerate versions of the tymoviral OP. The loss of OP during evolution may explain the phloem limitation of marafiviruses. Citrus sudden death-associated virus (CSDaV) is the only marafivirus with an additional ORF near the 3' end of the genome. This ORF almost completely overlaps the CP ORF and could encode a 16 kDa protein.

The three grass-infecting marafiviruses, MRFV, OBDV, and Bermuda grass etched-line marafivirus, are serologically related, but are not serologically cross-reactive with tymoviruses or more distantly related viruses. Despite the indications of genome variability mentioned above, the marafiviruses do form a phylogenetic group with interspecies relationships similarly close to those between the various tymoviruses (Fig. 3). Sequence relationships among the RP and CP ORFs clearly link the marafiviruses to the other members of the *Tymoviridae*. Like the tymoviral CPs, marafivirus CPs lack a cluster of basic aa at the N terminus.

Infection and Transmission

Marafi- and maculaviruses are phloem limited. The best-studied marafiviruses are MRFV and OBDV. They cause stunting and chlorotic leaf spots or streaks, general leaf discoloration, or enations on leaf and stem veins. Cytological symptoms are restricted to the phloem and adjacent parenchyma cells, with clearly discernible hyperplasia and hypertrophy. These viruses are not mechanically transmissible or transmissible through seed, but are vectored in nature by leafhoppers. Significantly, MRFV and OBDV are maintained for long periods and through molts in leafhopper vectors, and transmission can occur from viruliferous vectors over a period of several weeks. OBDV replicates in the aster leafhopper (*Macrostelus fascifrons*), and the transmission behavior of MRFV is also consistent with replication in the cicadellid leafhopper (*Dalbulus maidis*). MRFV is commonly associated and co-transmitted with maize stunt spiroplasma or maize bushy stunt phytoplasma in causing economically significant outbreaks of corn stunt syndrome. OBDV can also be co-transmitted with a phytoplasma. The presence of virus in the leafhopper vectors is not associated with detectable symptoms or loss of reproductive fitness.

The most economically significant marafivirus is probably CSDaV. This virus is believed to be the causative agent of the citrus sudden death syndrome, which has had devastating effects on orange trees in Brazil. Preliminary evidence suggests transmission by aphids. The grapevine-infecting tentative marafiviruses, Grapevine asteroid mosaic-associated virus and Grapevine rupestris vein-feathering virus, have no known insect vector.

Maculaviruses

Properties and Distinguishing Characteristics

Recent sequencing of the complete genome of GfKV supported the creation of the new genus *Maculavirus*. The distinguishing characteristics were the length of the GfKV genome, the absence of a tymobox/marafibox, the lack of a fused RP/CP ORF as present in marafivirus genomes, and the lack of phylogenetic clustering with either tymoviruses or marafiviruses. Grapevine red globe virus (GRGV) is a tentative member of the genus. Both viruses infect only *Vitis* species (grapevine and relatives). In common with marafiviruses, these maculaviruses are restricted to the phloem and are not sap transmissible. No insect vectors have been identified. As for all other members of the family *Tymoviridae*, maculaviruses produce ~29 nm particles with prominent surface features observable by EM. Top component and infectious bottom component particles are produced. GfKV infections are cytologically distinct from marafivirus infections through the presence of severely modified mitochondria ('multivesiculate bodies').

The genome of GfKV (7564 nt) is the longest among the members of the family *Tymoviridae*, and has the highest cytosine content (49.8%). The arrangement of RP and CP ORFs is like that of tymoviruses (Fig. 2). The RP ORF encodes a 215 kDa protein with replication-associated domains that present sequence relatedness to the tymoviral and marafiviral RPs. The aa sequence of the RdRp domain shows the closest relationship to sister genera (59% and 67% identities with the RdRps of a tymovirus and marafivirus, respectively).

The 24.5 kDa GfKV CP has 23%–31% sequence identity with CPs of tymoviruses and marafiviruses, and like other CPs of members of the family *Tymoviridae* it lacks a cluster of basic aa at the N-terminus. The GfKV genome encodes two additional proteins from ORFs that partially overlap the CP ORF in the 3' region of the genome. No functions for these putative proteins are predicted from sequence comparisons. Close relationship between GfKV and GRGV is rather weakly supported by sequence comparisons (Fig. 3).

The GfKV genome is probably capped at the 5' end and has a poly(A) tail at the 3' end, in common with most marafiviruses and PnMV. It is the only known member of the family *Tymoviridae* to lack a tymobox- or marafibox-like sequence. Nevertheless, two or more sgRNAs, ~1.3 and ~1.0 kb in length, are present in infected tissues. These RNAs appear to be packaged in both top- and bottom-component particles, in the latter case apparently together with the genomic RNA.

Poinsettia Mosaic Virus

Properties and Distinguishing Characteristics

PnMV possesses properties characteristic of both the tymoviruses and marafiviruses. The ~28 nm virus particles have the EM structure typical of the *Tymoviridae* and separate into typical top components containing the sgRNA and infectious bottom components. Like tymoviruses, PnMV is produced in high yield during infection, is not phloem-limited, and can be mechanically transmitted in the laboratory. Replication is associated with chloroplast cytopathy, though not with the appearance of the replication-associated vesicles typical of tymovirus infection. The properties and coding arrangement of the 6.1 kb RNA are more closely aligned with those of the marafiviruses (Fig. 2). The genomic RNA is polyadenylated, contains a marafibox-related putative sgRNA promoter, and possesses a single long ORF that encodes an RP/CP fusion protein (p221). No OP ORF is present. The 21–24 kDa PnMV CP is presumably expressed from the 0.65 kbp sgRNA; the involvement of potential cleavage of the RP/CP fusion protein to produce a second CP variant is not known. Although PnMV sequences are more closely related to the marafiviruses than tymoviruses, the relationships appear to be insufficiently close to warrant inclusion in the genus *Marafivirus* (Fig. 3).

In commercial poinsettia cultivation, PnMV is transmitted by vegetative propagation; the virus is not transmissible via seed or pollen. The natural host range is restricted to *Euphorbia* sp., especially poinsettia, *E. pulcherrima*. Symptoms appear seasonally, varying from unapparent to light mottling. PnMV is often associated with poinsettia cryptic virus (family *Partitiviridae*) and with a phytoplasma that is responsible for the desirable free-branching phenotype.

Bombyx Mori Latent Virus

Properties and Distinguishing Characteristics

Bombyx mori latent virus (BmLV) was initially identified in a cultured cell line (BmN) of the silk moth (*Bombyx mori*) by cDNA microarray. The full-length sequence is 6153 nt excluding the poly(A) tail. Putative isometric virions of ~28–30 nm were observed and were found to be infections to insect Sf-9 cells and tissues of *B. mori* larvae. The genome encodes a protein of 1747 aa residues containing the conserved MTR, PRO, HEL, and POL regions of tymovirus replication polyprotein. It shares 44% aa identity to GFkV. The single CP is encoded in a second ORF and is expressed from a 1.25 kb sub-genomic RNA. A third putative ORF is located at the 3' terminus of the genome and encodes a putative 15.5 kDa protein. The genome lacks the 'tymobox' or 'marafibox' sub-genomic promoter. Phylogenetic analysis of the replicase and CP sequences suggests that BmLV is a putative member of the family *Tymoviridae*, distinct from tymo- and marafiviruses, but closely related to GFkV. In the absence of additional data, it has been designated as an unassigned species in the family.

Glossary

Fibrillarin An abundant nucleolar protein that participates in the processing and modification of rRNAs and a methyltransferase.

Nucleolus A prominent subnuclear domain and the site of transcription of ribosomal RNA (rRNA), processing of the pre-rRNAs and biogenesis of pre-ribosomal particles, and

also participates in other aspects of RNA processing and cell function.

Phloem Plant vascular system used for rapid long-distance transport of assimilates and macromolecules.

Plasmodesmata Plant unique intercellular membranous channels that span plant cell walls linking the cytoplasm of contiguous cells.

Introduction

Umbraviruses differ from other plant viruses in that they do not encode a coat protein (CP), and thus no conventional virus particles are formed in the infected plants. The name of the genus *Umbravirus* is derived from the Latin *umbra*, which means a shadow, or an uninvited guest who comes with an invited one. This name reflects the way in which umbraviruses depend for survival in nature on an assistor virus, which is always a member of the *Enamovirus* or *Polerovirus* genera of the family *Luteoviridae*. For transmission between plants, the CP of the assistor virus forms aphid-transmissible hybrid virus particles encapsidating umbraviral RNA. In nature, each umbravirus is associated with one particular member of the family *Luteoviridae*, although in experiments trans-capsidation is not needed for umbravirus infection accumulation within infected plants because functions such as protection and movement of the virus RNA, both cell-to-cell and long distance, do not require the presence of the assistor virus or its CP. Moreover, under experimental conditions, mechanical transmission of umbraviruses can take place without the aid of an assistor virus. This implies that umbraviruses encode some product(s) that functionally compensate for the lack of a CP (see below).

Classification

Currently the genus *Umbravirus* includes nine distinct virus species which are accepted by ICTV taxonomy: *Carrot mottle virus* (CMoV) – the type species, *Carrot mottle mimic virus* (CMoMV), *Groundnut rosette virus* (GRV), *Ethiopian tobacco bushy top virus* (ETBTIV), *Lettuce speckles mottle virus* (LSMV), *Opium poppy mosaic virus* (OPMV), *Pea enation mosaic virus-2* (PEMV-2), *Tobacco mottle virus* (TMoV), and *Tobacco bushy top virus* (TBTIV). These viruses together with the tentative members of the genus *Umbravirus* are listed in [Table 1](#). Some of these viruses have been known since the early days of plant virology. The first to be described was TMoV, reported from Zimbabwe and Malawi in 1945. The most economically important umbravirus is GRV, which is endemic throughout sub-Saharan Africa. Sporadic, unpredictable outbreaks of groundnut rosette disease (actually caused by a satellite RNA of GRV) cause severe crop losses. Pea enation mosaic disease outbreaks are also sporadic and localized, but losses of nearly 90% in peas and up to 50% in field beans have been reported. One or both of the carrot-infecting umbraviruses probably occurs worldwide wherever carrots are grown, but they are uncommon in commercial crops because the insecticides used to control carrot fly also control the aphid vectors of CMoV and CMoMV. LSMV is reported only from California, USA.

Virion Structure

Although in plants infected with umbraviruses unaccompanied by the assistor virus no virions are formed, the infectivity of CMoV and GRV in buffer extracts of infected leaves is surprisingly stable: survives for several hours at room temperature and is resistant to treatment with ribonuclease. It is however, sensitive to a treatment with organic solvents, suggesting that lipid-containing structures are involved in protection of umbravirus RNA. Indeed, in plants infected with a number of umbraviruses, including CMoV, enveloped structures ~50 nm in diameter were observed. An infective fraction from GRV-infected tissue contained complexes with a buoyant density of 1.34–1.45 g/cm³ consisting of filamentous ribonucleoprotein particles, composed of the umbraviral ORF3 protein (see below) and virus RNA, embedded in a matrix ([Fig. 1](#)). The relationship between these two kinds of structure is unclear.

Table 1 Virus members of the genus *Umbravirus*

<i>Virus (isolate)</i>	<i>Abbreviation</i>	<i>Accession no.</i>	<i>Assistor virus</i>
<i>Carrot mottle mimic virus</i> Carrot mottle mimic virus-Australia	(CMoMV-AU)	U57305	<i>Carrot red leaf virus</i>
<i>Carrot mottle virus</i> Carrot mottle virus-Weddel	(CmoV-We)	FJ188473	<i>Carrot red leaf virus</i>
<i>Ethiopian tobacco bushy top virus</i> Ethiopian tobacco bushy top virus 18–2 Satellite RNA	(ETBTv18–2)	KJ918748 KJ918747	<i>Potato leafroll virus</i>
<i>Groundnut rosette virus</i> Groundnut rosette virus-MC1 Satellite RNAs	(GRV-MS1)	Z69910 Z29702-Z29711	<i>Groundnut rosette assistor virus</i>
<i>Lettuce speckles mottle virus</i> Lettuce speckles mottle virus-California Opium poppy mosaic virus Opium poppy mosaic virus-PHEL5235	(LSMV-CA) (OPMV-PHEL5235)	MG182693	<i>Beet western yellows virus</i> Opium poppy mosaic-associated virus
<i>Pea enation mosaic virus-2</i> Pea enation mosaic virus-2-WGS Bean yellow vein-banding virus Satellite RNA	(PEMV-2-WGS) (BYVbV)	U03563 U03564	<i>Pea enation mosaic virus-1</i>
<i>Tobacco bushy top virus</i> Tobacco bushy top virus-Baoshan	(TBTv-Bao)	AF402620	<i>Tobacco vein distorting virus</i>
<i>Tobacco mottle virus</i> Tobacco mottle virus-Zimbabwe	(TMoV-ZW)	AY007231	<i>Tobacco vein distorting virus</i>
<i>Tentative members in the genus</i> <i>Sunflower crinkle virus</i> <i>Sunflower yellow blotch virus</i> <i>Tobacco yellow vein virus</i>	(SuCV) (SuYbV) (TYVV)		

**Fig. 1** Electron microphotograph of a section of a *Nicotiana benthamiana* cell expressing GRV ORF3 protein. The section shows a complex of filamentous RNP particles embedded in an electron dense matrix. The section was labeled by *in situ* hybridization with an RNA probe specific for viral RNA. Bar, 100 μ m.

Genome Organization and Expression

The genome of umbraviruses consists of single linear segment of positive-sense single stranded RNA (ssRNA) (**Fig. 2**). The complete genomic RNA sequences of umbraviruses are of 4019–4253 nt in length. There is no polyadenylation at their 3' termini and there is no information about modifications of their 5' termini. At the 5' end, a very short non-coding sequence precedes ORF1, which encodes a putative 31–37 kDa protein. The ORF2, which overlaps the 3' end of ORF1, potentially encodes a

Fig. 2 Organization and expression strategy of GRV genome. Translation of the ORF1 and the ORF2 with a frameshift event results in production of the ORF1-ORF2 frameshift protein; subgenomic RNA (sgRNA) synthesis is required for expression of the ORF3 and ORF4. Solid lines represent RNA molecules, boxes represent open reading frames (ORFs), corresponding translation products are shown below. RdRp, RNA-dependent RNA polymerase; FS, – 1 frameshift signal.

63–65 kDa protein, but lacks an AUG initiation codon. It is likely that ORF1 and ORF2 are translated as a single 94–98 kDa protein by a –1 translational frameshifting mechanism; the sequence associated with frameshifting events in genomes of several animal and plant RNA viruses is found in the region at the 3' end of the ORF1. The predicted amino acid sequence of the ORF2-encoded product includes an RNA-dependent RNA polymerase (RdRp) domain typical to that of other members of the family *Tombusviridae*, containing all eight conserved motifs of RdRps of positive-strand RNA viruses.

A short untranslated stretch separated ORF2 from ORF3 typical to that of and ORF4 which are almost completely overlap in different reading frames and each encode a 26–29 kDa products. The ORF4 contains motifs characteristic of the cell-to-cell movement proteins (MPs) of plant viruses, in particular with those of cucumoviruses. The ORF3 products possess up to 50% homology to each other but shows no significant similarity to any other viral or non-viral product. The ORF3 and ORF4 are translated from subgenomic RNA, the 3' terminal RN

A of the appropriate size was detected in the GRV infected plant tissue. It should be pointed out that the sequenced genomes of umbraviruses do not encode a potential CP(s). The essential role of the ORF3-ORF4 block in movement of umbraviruses within plants has been experimentally demonstrated and is discussed below.

The 3' untranslated region of PEMV2 contains three 3' proximal, cap-independent translation enhancers (3'CITEs), which are required for proper virus translation. Efficient translation of the ORF3 and ORF4 proteins from the sgRNA requires all three (3'CITEs), whereas translation of the genomic requires only two 3'CITEs.

Similarity With Other Taxa

The only gene conserved across all RNA viruses is the RdRp which is cenral to virus replication and existence, therefore RdRp was used to investigate global phylogenetic relationships between viral taxonomic groups. Based on the RdRp phylogeny, umbraviruses were included in the family *Tombusviridae*, alongside with the members of the genera *Alphacarmovirus*, *Alphanecrovirus*, *Aureusvirus*, *Avenavirus*, *Betacarmovirus*, *Dianthovirus*, *Gammacarmovirus*, *Macanavirus*, *Machlomovirus*, *Panicovirus*, *Pelarspovirus*, *Tombusvirus*, and *Zeavirus*, all of which infect plant hosts.

A recent analysis of the RdRp sequences of all known RNA viruses showed that the family *Tombusviridae*, together with the genus *Luteovirus* and the family *Carmotetraviridae*, with which it has highest RdRp homology, belongs so-called "Branch 3" group of global RdRp and reverse transcriptase phylogeny, which also includes subset of positive-sence RNA viruses of viruses, such as "alphavirus supergroup", "flavivirus supergroup" and nodaviruses. Members of the Branch 3 infect hosts across all eukaryotic kingdoms.

Replication

Replication of umbravirus RNA presumably involves the ORF2-encoded RdRp. Leaves of plants infected with umbraviruses contain abundant dsRNA including a major species of about 4.4–4.8 kbp corresponding in size to that expected for double stranded form of the viral genomic RNA which may be umbravirus RNA replication intermediate. No other details of the replication mechanism have been elucidated.

Satellite RNA

Satellite RNAs are associated with some umbraviruses. In the case of GRV, satellite RNA is found in all naturally occurring isolates, and is primarily responsible for the symptoms of groundnut rosette disease. GRV satellite RNA is a ssRNA of about 900 nt which relies on GRV for its replication and, more unusually, is also required for the *Groundnut rosette assistor virus* (GRAV)-dependent aphid transmission of GRV. Thus, unlike most virus satellite RNAs, it is essential for the biological survival (though not the replication) of its helper virus. The role of the satellite RNA in the transmission process is to mediate transcapsidation of GRV RNA by GRAV protein to form stable aphid-transmissible hybrid virus particles. Although different GRV satellite RNA variants contain up to five potential ORFs, none of the ORFs is essential for any of the functions and biological properties that have been ascribed to GRV satellites. In contrast, the satellite RNA that is associated with some isolates of PEMV-2 is not required for transcapsidation of PEMV-2 RNA by the CP of its assistor virus PEMV-1 or for aphid transmission of the hybrid particles, and other umbraviruses, such as CMoV, do not have satellite RNAs, yet are transcapsidated by their assistors and thus transmitted by aphids. The reasons for these differences have not been explained.

Cell-to-Cell Movement Function

The highly conserved ORF4-encoded proteins of umbraviruses exhibit significant sequence similarity with cell-to-cell movement proteins (MPs) of other plant viruses, in particular the 3a proteins of cucumoviruses. Therefore it has been suggested that this protein involved in cell-to-cell trafficking of umbravirus RNA through plasmodesmata. This suggestion has been confirmed by a number of genetic, cytological and biochemical approaches. By using the gene replacement strategy, it was demonstrated that the GRV ORF4 protein could functionally replace the MPs of unrelated viruses, *Potato virus X* (PVX) (all the products encoded by the triple gene block and the CP) and *Cucumber mosaic virus* (CMV) (the 3a MP and the CP). Localization of the GRV ORF4 protein has much in common with localization of MPs of other plant virus groups. The green fluorescent protein (GFP)-tagged GRV ORF4 protein targeted to plasmodesmata ([Fig. 3\(A\)](#)). Also, this protein formed extending tubular structures on the surface of protoplasts infected either with GRV or with the heterologous virus expressing the GFP-tagged GRV ORF4. The GRV ORF4 protein binds to RNA *in vitro* in non-cooperative manner which may make the viral RNA of the ribonucleoprotein (RNP) complex accessible for translation and replication.

Fig. 3 Confocal laser scanning images showing the localization of (A) GRV ORF4 protein fused to GFP to plasmodesmata (shown by arrows) (bar, 25 μ m) and (B) GRV ORF3 protein fused to GFP to the nucleolus (No) and cytoplasmic inclusions containing ORF3 protein RNP particles (cRNP) (bar, 10 μ m).

Phloem-Dependent Long-Distance Movement Function

One of the striking features of umbraviruses is their ability to move long distance within a plant without having a conventional CP. Involvement of CPs in long distance movement of viral infection was shown for a number of plant viruses, including *Tobacco mosaic virus* (TMV) which utilizes the CP exclusively for its long-distance but not cell-to-cell movement function. By using the gene replacement strategy it was demonstrated that the ORF3 proteins of GRV, PEMV-2 and ToMV were able to functionally substitute the TMV CP in the long-distance movement process. The hybrid TMV mutants expressing the umbraviral ORF3 proteins were able to move rapidly within through the phloem. It was also shown that specific mutations in the ORF3 protein of PEMV-2 abolish ability of this virus to move long distance without affecting its cell-to cell spread within inoculated leaves.

It should be noted that mechanisms of the long-distance movement facilitated by umbraviral ORF3 proteins is different from those mediated by suppressors of RNA silencing such as the 2b proteins of cucumber mosaic virus and the HC-Pro protein of potyviruses. Rather than supporting virus infection by suppressing the host RNA-mediated response, the ORF3 protein seems to protect RNA by binding to viral RNA. It was shown that the ORF3 proteins of GRV, PEMV-2 and ToMV increase stability of viral RNA and protect it from RNases. Immunogold labeling and *in situ* hybridization experiments showed that the GRV ORF3 protein accumulated in cytoplasmic granules consisted of filamentous RNP particles composed of the ORF3 protein and viral RNA (Fig. 1). It has been suggested that these particles may be a form in which viral RNA moves long-distance through the phloem. Also the ORF3-containing RNP complex may protect viral RNA from nucleases and RNA silencing machinery.

Involvement of Nucleolus in Umbravirus Systemic Infection

In addition to cytoplasmic granules, the GRV ORF3 protein was also found in nuclei, preferably targeting nucleoli (Fig. 3(B)). Sequence analysis of the ORF3 proteins of umbraviruses revealed the presence of both nuclear localization signal (NLS) and nuclear export signal (NES), functional role of which in nuclear import and export of the GRV ORF3 has been confirmed experimentally by the genetic analysis. Functional analysis of ORF3 protein mutants revealed a correlation between the ORF3 protein nucleolar localization and its ability to form the RNP particles and transport viral RNA long distances. It was also shown that the ORF3 protein directly interacts with a nucleolar protein, fibrillarin, re-distributing it from the nucleolus to cytoplasm and such an interaction is absolutely essential for umbravirus long-distance movement through the phloem. The umbraviral ORF3 protein utilizes trafficking pathways involving Cajal bodies to enter the nucleolus and, along with fibrillarin, exit the nucleus to form viral 'transport-competent' RNP particles in the cytoplasm.

Interaction With Assistor Virus

Although umbraviruses accumulate and spread very efficiently within infected plants, they depend on assistance of luteoviruses for their survival in nature as they require encapsidation by luteovirus CP for horizontal transmission by aphids. In its turn, umbraviruses facilitate movement of phloem limited luteoviruses to and from the phloem, as well as cell-to-cell movement of luteoviruses between mesophyll and epidermal cells. It was shown that such an ability to promote cell-to-cell movement of luteoviruses is a unique feature of the umbraviral ORF4 MP. Moreover, the ORF4 MP of GRV can facilitate cell-to-cell movement of *Potato leafroll luteovirus* even when expressed from heterologous PVX or CMV genomes. In most instances, the luteovirus partner does not depend on the umbravirus infection for survival in nature. A complex consisting of PEMV-1 (the genus *Enamovirus*, family *Luteoviridae*) and PEMV-2 is a notable exception. Unlike other members of the family *Luteoviridae*, PEMV-1 on its own lacks the ability to move, even through the phloem; both long-distance and cell-to-cell movement functions of PEMV-1 are provided by the umbraviral component of the complex, PEMV-2. Such a strong mutual dependence and adaptation between umbraviruses and luteoviruses suggest a long co-evolution, which had resulted in establishing a range of complexes from facultative co-existence to complete dependence of PEMV-1.

Host Range

Individual umbraviruses are confined in nature to one or two host plant species. For example, groundnut is the only known natural host of GRV and entire rosette disease complex (GRV, its satellite RNA and GRAV). Experimental host ranges of umbraviruses are broader but still restricted. The symptoms induced in infected plants are usually mottles and mosaics.

Transmission

In nature, umbraviruses are transmitted by aphids, but only from plants that also infected with an assistor member of the family *Luteoviridae*. The mechanism of the dependent transmission is the encapsidation of the umbraviral RNA by the CP provided by the assistor virus. Hence, the transmission of the dependent umbravirus occurs in the same persistent (circulative, nonpropagative) manner as that of the luteovirus-assistor.

Prevention and Control

For the avoidance of pea enation mosaic disease, it is recommended that pea or faba bean crops should be sited away from alfalfa and clover fields. Early sowing and close spacing can reduce groundnut rosette disease incidence, probably by inhibiting the landing response of the vector. This approach is also effective against tobacco rosette disease. However, the best control approach is to use resistant cultivars if they are available. Resistance to GRV controlled by two independent recessive genes has been found and groundnut lines possessing this resistance have been developed. A possibility for the future is the deployment of transgenic forms of resistance. Strategies for engineering transgenic resistance against umbraviruses include the transformation of plants with translatable or non-translatable sequences from the umbraviruses themselves or their satellite RNAs.

Glossary

Big-vein disease of lettuce A lettuce disease that induces abnormal dilation or enlargement of a vein or the artery in a lettuce leaf, decreasing market value and reducing the proportion of harvestable lettuce. The name 'big-vein disease' refers to the appearance of the major symptoms.

L protein The main subunit of the polymerase complex, responsible for most of the functions required for transcription and replication: RNA-dependent RNA polymerase, mRNA 5'-capping, 3'-poly(A) synthesis, and protein kinase activities.

Necrotic syndrome of lettuce A lettuce disease that induces necrotic rings and spots in lettuce leaf and root

under a hydroponic culture of a nutrient film technique, decreasing market value and reducing the yield of lettuce.

Olpidium virulentus A obligate parasitic root-infecting fungus and a member of the *Chytridiomycetes* that seldom appears to be deleterious to the host plants but functions as vector of plant viruses.

Stop-and-start model A model for RNA synthesis of nonsegmented negative-sense RNA viruses that the viral polymerase complex transcribes a gene, polyadenylates and releases mRNA, and reinitiates transcription of the next gene under the direction of the gene-junction sequence.

Introduction

The big-vein disease of lettuce (*Lactuca sativa* L.) was first reported in 1934. The causal agent was postulated to be a root-infecting virus, but the virus particles have remained unidentified for more than half a century. In 1983, a rod-shaped virus was found in field-grown lettuce showing big vein-band chlorosis (Fig. 1). Because the rod-shaped virus is always associated with big-vein-affected lettuce, the virus was regarded as the agent that induced big-vein disease, without it being confirmed that the virus alone actually induced big-vein symptoms in lettuce. The rod-shaped virus was named Lettuce big-vein virus and was classified as the type species of a new genus *Varicosavirus*, which was established by the International Committee on the Taxonomy of Viruses in 2000.

A second virus, Mirafiori lettuce big-vein virus (MLBVV, genus *Ophiovirus*), has been found in commonly coinfecting field-grown lettuce showing big-vein symptoms. Mechanical inoculation of partially purified MLBVV-preparation and transmission experiments using MLBVV- or Lettuce big-vein virus-carrying fungal vectors independently showed that MLBVV, but not Lettuce big-vein virus, was the causal agent of big-vein disease. For these reasons, lettuce big-vein virus was renamed lettuce big-vein associated virus (LBVaV) in 2005.

LBVaV does not seem to induce vein-band chlorosis in lettuce, which is the characteristic symptom of the big-vein disease. However, LBVaV induces necrotic rings and spots in lettuce under a hydroponic culture of a nutrient film technique and it has become clear that the virus is the causal agent of the necrotic syndrome of lettuce.

Stunt disease of tobacco (*Nicotiana tabacum* L.) reported so far only in Japan was first recorded in 1931 as a seed-bed disorder. Stunt disease has seriously damaged tobacco leaf production in Japan until the 1960s, when the disease was found to be transmitted by an obligate parasitic soil-borne fungus and tobacco growers paid more attention to tobacco seed-bed sanitation.

Fig. 1 Electron micrograph of Lettuce big-vein associated virus. Transmission electron micrograph of a negative-stained purified virus preparation. The bar represents 100 nm.

Tobacco with stunt symptoms invariably has a varicosavirus, and mechanical inoculation of tobacco seedlings with partially purified virus-preparation leads to typical tobacco stunting; Tobacco stunt virus (TSStV) is regarded as the causal agent of tobacco stunt disease. Because of marked differences in host reactions, LBVaV and TSStV were considered to be distinct viruses. However, a comparison of partial sequences of LBVaV and TSStV suggests now that TSStV is a strain of LBVaV.

Taxonomy and Classification

The floating genus *Varicosavirus* was first established by the International Committee on the Taxonomy of Viruses in 2000. Even though LBVaV is a two-segmented negative-sense RNA virus with a fragile non-enveloped rod shape, LBVaV shares several features with plant rhabdoviruses, which generally have linear non-segmented negative-sense RNA genomes and large enveloped particles with a prominent fringe of peplomers. On the base of genome structures and amino acid sequence comparisons between LBVaV and other plant rhabdoviruses, the taxonomic position was re-evaluated by the current committee in 2018, and the genus *Varicosavirus* is now classified in the family *Rhabdoviridae*. *Lettuce big-vein associated varicosavirus* is the type species of this genus, and LBVaV and three tentative viruses, have been tentatively placed into the genus; *Alopecurus myosuroides varicosavirus* 1, Tobacco stunt virus, and Red clover associated varicosavirus.

LBVaV particles are fragile non-enveloped rods about 18 nm in diameter, with modal lengths of 320–360 nm. Virus particles have a central canal about 3 nm in diameter and an obvious helix with a pitch of about 5 nm, appearing similar to the inner striated nucleocapsid core of rhabdoviruses. Virus particles are very unstable *in vitro*, so the helix of particles, especially those in purified preparations, tends to loosen and become partially uncoiled, even in preparations fixed with glutaraldehyde.

LBVaV was initially believed to have a divided genome consisting of two segments of double-stranded RNA, approximately 7.0 and 6.5 kbp. Once LBVaV purification was established and the complete nucleotide sequence of LBVaV determined, a precise reinvestigation of LBVaV genome components showed that LBVaV is not a double-stranded RNA virus but a single-stranded RNA virus with a bipartite genome. Negative-sense and positive-sense RNAs are separately encapsidated in the virions and the negative-sense RNA is predominant.

Criteria for membership in the genus are non-enveloped rod-shaped particles, a two-segmented negative-sense RNA genome, and transmission through moist soil by motile zoospores of the obligate parasitic soil-borne fungus, *Olpidium virulentus*.

Genetics and Evolution

Nucleotide sequence and genome mapping studies showed that the LBVaV genome consists of 12878 nucleotides, divided into two segments (Fig. 2). The larger segment (RNA1) contains antisense information for a small hypothetical protein and a large gene that encodes the large protein (L) of 2040 amino acids. The smaller LBVaV genome segment (RNA2) contains antisense information for five major genes, which have coding capacities for 397, 333, 290, 164, and 368 amino acids, respectively.

L Protein Encoded on RNA1

As with other negative-sense RNA viruses, the L protein of LBVaV is positively charged and contains RNA-directed RNA polymerase (RdRp) and RNA binding domains. Alignment of the L protein sequence with those of several other negative-sense RNA viruses shows the conservation of functional RdRp motifs (Fig. 2). The L protein of LBVaV contains conserved premotif A, which presumably plays an important role in RNA template binding and positioning, and four motifs that correspond to motifs A, B, C, and D, thought to comprise the palm and finger regions of the polymerase active site in negative-sense RNA viruses. A putative ATP binding motif, Kx₁₇GxGxG, proposed to be associated with polyadenylation or protein kinase activity, is present at position 1643–1665. LBVaV has been experimentally shown to transcribe 3'-polyadenylated mRNAs.

Fig. 2 Schematic representation of the genome organization of a negative-sense arrangement of genes encoded in the genome of Lettuce big-vein associated virus. Gene-junction regions, including the gene-end sequence (I), the intergenic sequence (II), and the gene-start sequence (III), are shown above negative-sense genomic RNAs.

Fig. 3 Comparison of conserved motifs of the L protein among LBVaV, eight rhabdoviruses, and two plant segmented negative-sense RNA viruses. The amino acid sequence of the L protein of LBVaV is shown at the top followed by amino acid sequences of the cytorhabdoviruses Lettuce necrotic yellows virus (LNyV) and Northern cereal mosaic virus (NCMV), the nucleorhabdoviruses Sonchus yellow net virus (SYNV) and Rice yellow stunt virus (RYSV), and the vertebrate rhabdoviruses Vesicular stomatitis Indiana virus (VSIV)(now Indiana vesiculovirus), Rabies virus (RABV)(now Rabies lyssavirus), Bovine ephemeral fever virus (BEFV)(now Bovine fever ephemerovirus), Infectious hematopoietic necrosis virus (IHNv)(now Salmonid novirhabdovirus), the orthotospovirus Tomato spotted wilt virus (TSWV) and the tenuivirus Rice stripe tenuivirus (RSV). Numbers at the beginning of lines indicate the position of the first displayed amino acid. Numbers within brackets indicate the numbers of amino acids not represented in the figure. Conserved residues recognized previously for L proteins of negative-sense RNA viruses are shown in bold letters and residues characteristic of the division between nonsegmented and segmented negative-sense RNA viruses are underlined.

The L protein is the only region sufficiently conserved to enable evolutionary relationships to be established among negative-sense RNA viruses. Even though LBVaV is segmented, most of the conserved motifs previously identified in the L proteins of non-segmented negative-sense RNA viruses are conserved in the L protein of LBVaV (Fig. 3), particularly the conserved sequence GDN in motif C, which likely constitutes the evolutionary and functional equivalent of the sequence GDD in polymerases of positive-sense RNA viruses. This is in striking contrast to segmented negative-sense RNA viruses whose polymerase has the conserved sequence SDD. Amino acids G at position 662 and W at position 671 in motif B, specific to the nonsegmented viruses, are also conserved in the L protein of LBVaV. Tetrapeptide E(F/Y)xS, located downstream from motif D, which is specifically conserved in polymerases of segmented negative-sense RNA viruses, is not found in the L protein of LBVaV.

Phylogenetic analysis of the partial L proteins between LBVaV and rhabdoviruses shows that the L protein of LBVaV clusters within the family *Rhabdoviridae*, and that the L protein of LBVaV is more distantly related to those of plant rhabdoviruses than they are to each other, but is more closely related to those of plant rhabdoviruses than those of vertebrate rhabdoviruses (Fig. 4).

Proteins Encoded on RNA2

The first gene at the 3' end of genomic RNA encodes the coat protein (CP), which shows low but significant similarity to the nucleocapsid (N) proteins of plant rhabdoviruses. Most other genes encode hypothetical proteins with unknown functions, while the third encoded protein has several properties related to a viral cell-to-cell movement protein (MP).

Gene Bank database homology searches using the amino acid sequence of the CP of LBVaV consistently retrieve N proteins of rhabdoviruses. Phylogenetic analysis between the CP of LBVaV and N proteins of rhabdoviruses shows that the CP clusters within the family *Rhabdoviridae*, and that the CP is most closely related to the N protein of a fish rhabdovirus, infectious hematopoietic necrosis virus (IHNv), and to a lesser extent to that of plant rhabdoviruses. In a PSI-BLAST search against the ProDom protein domain database, the carboxy-terminal part of the CP shows similarity to two domains, one is the homologous domain among N proteins of plant rhabdoviruses and another is the homologous domain among those of fish rhabdoviruses.

Fig. 4 Computer-generated tree illustrating phylogenetic relationships between LBVaV and selected rhabdoviruses derived from aligned amino acid sequences of the partial L protein between premotif A and motif D. The tree was generated using the neighbor-joining method of the MEGA6 software. The percentage of replicate trees in which the associated taxa clustered together in the bootstrap test (1000 replicates) are shown. The evolutionary distances were computed using the Poisson correction method. Borna disease virus (BDV)(now Mammalian 1 orthobornavirus) is used as an out-group. See Fig. 3 for abbreviations of virus names.

The protein 2 of LBVaV is coded in the second gene that corresponds in position to the gene coding for the phosphoprotein (P) of rhabdoviruses, which interacts with the N protein and the L protein and constitutes the active polymerase complex. The predicted overall structure of the protein 2 and P proteins, assessed by amino acid composition and by relative hydropathicity distribution, is similar. Coiled-coil regions of P proteins of rhabdoviruses have been used to predict the regions for their oligomerization and interaction. Analysis using the COILS2 program predicts that the protein 2 contains three possible coiled-coil regions at the amino-terminal (aa 29-48), central (aa 122-135), and carboxy-terminal (aa 239-253) domains that are similar in position, to those in the P protein of Sonchus yellow net virus (SYNV). A detailed analysis of phosphorylation sites for cellular casein kinase II in the P protein of vesicular stomatitis Indiana virus (VSIV) confirmed five of ten potential phosphorylation sites of the P protein, which may regulate transcription and replication, are required to form the active polymerase complex. The protein 2 of LBVaV also has ten potential phosphorylation sites, and the five essential phosphorylation sites for the P protein of VSIV are conserved in positions similar to those of LBVaV. A predominantly basic 20-amino-acid-long region near the carboxy-terminus of the P protein of VSIV, which may serve as an attachment domain for combination with the L protein, also occurs in the carboxy-terminal region of the protein 2 of LBVaV.

The protein 3 of LBVaV is encoded in the third gene that corresponds in position to the gene coding for the MP of plant rhabdoviruses, which is essential for the plant viruses to assist in cell-to-cell movement through the host plant plasmodesmata. The protein 3 had a predicted structure similar to the 30K superfamily MP consensus structure and consisted of a series of β -elements flanked by an α -helix on each end. Our unpublished data of a transient expression using the GFP-fused P3 protein in epidermal cells of *Nicotiana benthamiana* showed the localization of the P3 protein to the plasmodesmata. The movement hypothesis for the protein 3 has been reinforced by our *trans*-complementation experiment with movement-defective tomato mosaic virus in *N. benthamiana* leaves: the protein 3 facilitated the spread of the movement-defective mutant from initially infected cells through two or more cell layers.

The protein 5 of LBVaV, which corresponds in position to the gene coding for the glycoprotein (G) of plant rhabdoviruses, has also little direct relatedness to the envelope-associated glycoproteins of rhabdoviruses. The protein 5 sequence does not contain any canonical sites for N-linked glycosylation, and does not contain the N-terminal signal peptide or carboxy-terminal hydrophobic transmembrane anchor domains, which are common among G proteins of rhabdoviruses. Conservation of cysteine residues is another common feature of G proteins of rhabdoviruses. Alignment using the Clustal W program for G proteins with plant rhabdoviruses shows that eleven cysteine residues are situated at conserved positions. In the case of LBVaV, six of ten cysteine residues are located at similar conserved positions in G proteins of plant rhabdoviruses. The protein 5 of LBVaV may thus result from the degeneration of G proteins of plant rhabdoviruses. The six cysteine residues in the protein 5 of LBVaV that may play an important role in activities, such as forming the secondary structure of G proteins of plant rhabdoviruses appear to have been stringently conserved among the protein 5 of LBVaV and G proteins of plant rhabdoviruses. The other five cysteine residues, however, appear to have evolved extensively to accommodate diverse host requirements and vector adaptations.

Transcription Termination/Initiation Strategy

LBVaV transcribes capped and polyadenylated mono-cistronic mRNAs. In the gene-junction regions of LBVaV, transcription termination/polyadenylation and initiation signal sequences comparable to those of rhabdoviruses are recognized (Fig. 5), suggesting that LBVaV and rhabdoviruses may use a similar mechanism of transcription, a stop-and-start model, to differentially express individual genes from a contiguous virus genome.

		I	II	III
LBVaV	TypeA	UNCAUUUUUUU	G (N) _x	CUCU
	TypeB	AAUCUUUUUU		
LNyV		AUUCUUUUU	G (N) _x	CUCU
NCMV		AUUCUUUUU	GA	CUCU
SYNV		AUUCUUUUU	GG	UUGW
RYSV		AUUAUUUUU	GGG	UUGU
VSIV		AUACUUUUUUU	GA	UUGU
RABV		GYACUUUUUUU	G (N) _x	UUGU
IHNV		URUCUUUUUUU	G/A	CCRW

Fig. 5 Comparison of the gene-junction regions between LBVaV and selected rhabdoviruses. Gene-junction regions are separated into three sequences: I is the gene-end sequence that constitutes the poly(U) tract at the 3' end of each gene on negative-sense genomic RNAs and plays the role of a transcription termination/polyadenylation signal; II is the short intergenic sequence that is not transcribed during mRNA synthesis; and III is the gene-start sequence that constitutes the initiation site for transcription of each mRNA. Bold type in viral sequences indicates consensus nucleotides, R and W indicate A/G and A/U, and (N)_x corresponds to a variable number of nucleotides. See Fig. 3 for abbreviations of virus names.

The gene-junction regions of LBVaV are grouped into three elements: a gene-end sequence (I) at the 3' end of each gene on the genomic template, which is required for transcription termination/polyadenylation; a short non-transcribed intergenic sequence (II), which is not represented in mRNAs and separates each gene; and a gene-start sequence (III) located at the beginning of each subsequent gene, which plays an important role in transcription initiation. Gene-end sequences of rhabdoviruses consist of an A-U rich region, a cytidylate, and a poly(U) tract. The poly(U) tract is thought to be a template for the poly(A) tail of mRNA due to reiterative transcription or slippage. The gene-end sequences of LBVaV are either 3'-UNCAUUUUUUU-5' (Type A) or 3'-AAUCUUUUUUU-5' (Type B), reminiscent of those observed in other rhabdoviruses. When the gene-end sequence of LBVaV is Type A, transcription of the next gene is initiated immediately after a single nucleotide G, while for Type B, the two genes (genes 5 and L) are located at the 5'-most ends of each RNA (negative-sense) or transcription is reinitiated after a long 42 nt intergenic sequence located between genes 4 and 5, suggesting that the two variations of the gene-end sequences may influence signaling initiation of downstream mRNA synthesis as reported for VSIV in which the gene-end sequence plays an important role both in transcription termination/polyadenylation and in reinitiating transcription of downstream genes.

In contrast to other rhabdoviruses, including nucleorhabdoviruses whose gene-start sequence in the gene-junction regions is 3'-UUUGU-5', the conserved gene-start sequence of LBVaV is 3'-CUCU-5'. Sequence 3'-CUCU-5' is also conserved in the gene-junction regions of the cytorhabdoviruses lettuce necrotic yellows virus and northern cereal mosaic virus, suggesting that sequence 3'-CUCU-5' may be important in acting as a transcription initiation signal for both LBVaV and these cytorhabdoviruses, which replicate in the cytoplasm of plant cells.

Host Range and Geographic Distribution

Fungal vector transmission experiments in the greenhouse have shown that LBVaV systemically infects seven plant species in four families, and the infected plants including lettuce do not show any symptoms. However, the virus induced necrotic rings and spots in lettuce in hydroponic culture.

In contrast, the experimental host range of TSIV encompasses 41 species in nine dicotyledonous families by mechanical inoculation and 35 plant species in 13 families through fungal vector transmission. The virus does not infect lettuce, but induces vein clearing, vein necrosis, mottling, and stunting in many *Nicotiana* species.

LBVaV is widespread in cool to temperate regions and several parts of subtropical regions in Europe, Asia, Australia, and North and South America, but TSIV has only been reported in Japan.

Transmission and Vectors

LBVaV is transmitted through motile zoospores of an obligate parasitic soil-inhabiting fungus. LBVaV is very stable in soil within long-lived resting fungal spores for 20 years or more, but it is remains unclear whether the virus replicates inside fungal spores.

In 1878, the natural vector of LBVaV was reported to be *Olpidium brassicae* (Wor.) Dang. *O. brassicae* was first found in a cabbage (*Brassica oleracea*) root and the specific name of the fungus is derived from the genus name of the cabbage. Several strains of *O. brassicae* that differ significantly in host specificity, morphology, and virus transmissibility have been recognized, particularly a crucifer strain, which readily multiplies in roots of crucifer plants such as cabbage and mustard, and a noncrucifer strain that can not multiply in roots of crucifer plants. The crucifer strain is host-specific and the non-crucifer strain is highly polyxenous. Morphologically, zoosporangia and exit tubes of the crucifer strain differ slightly from those of the noncrucifer strain. The non-crucifer strain is a vector of the soil-borne viruses MiLV and tobacco necrosis virus, but the crucifer strain fails to transmit these viruses. Furthermore, the crucifer strain shows sexual reproductivity, although the noncrucifer strain does not reproduce sexually. Zoospores from a single-sporangium isolate of the crucifer strain do not develop a resting spore, but after mating between different mating (sexual) types, a resting spore form. In contrast, zoospores from the noncrucifer strain develop a resting spore without mating. Based on these differences, the crucifer and noncrucifer strains have been divided into two distinct species, but this

proposal has long been neglected. Recent rDNA-ITS analysis of *O. brassicae* strongly supported the hypothesis that crucifer and non-crucifer strains belong to separate species rather than being strains of the same *Olpidium* species, and a new species name, *O. virulentus*, has been proposed for the non-crucifer strain. The non-crucifer strain was confirmed to be a vector of LBVaV, although there is no reliable evidence that the crucifer strain (*O. brassicae*) is capable of transmitting LBVaV.

RdRp RNA-dependent RNA polymerase
RTD Read-through domain
sgRNA Sub-genomic RNA
ssRNA single-stranded RNA
TGB Triple gene block
UTR Untranslated region
VSR Viral suppressor of RNA silencing

Glossary

126-kDa protein The first protein expressed during tobamovirus infection, it has methyl-transferase and helicase domains, but lacks a polymerase domain. Read-through of the stop-codon of the open reading frame (ORF) encoding 126 kDa protein results in translation of the larger the 183 kDa protein, which has a polymerase domain.

Alpha-like viruses A group of viruses in the proposed classification of positive-stranded RNA viruses based on the sequence similarities and arrangement of domains of RNA-dependent RNA polymerase. Three groups have been recognized: the picorna-like group, the flavi-like group and the alpha-like group. Alpha-like group is named after the genus *Alphavirus* of the family *Togaviridae*.

Cross-protection A phenomenon whereby prior infection by one virus strain (the primary strain) can prevent or limit multiplication of another virus strain (the secondary strain) or a closely related virus. For this purpose, protecting strains (the primary strains) should cause attenuated symptoms and should reduce marketable yields only slightly. A few attenuated virus strains have been commercially used as a “vaccine”.

Cross-protection has been applied in the fields to control poty-, tobamo- and closteroviruses. The phenomenon was first reported with Tobacco mosaic virus (TMV) in 1929.

Defective interfering RNAs Subviral agents produced during replication of RNA viruses. Defective interfering (di) RNAs are parasitic RNAs because they take advantage of the parent virus-coded protein for their multiplication. These RNAs are called “defective” because they have lost the

capacity to code for the proteins needed for independent replication and thus are defective in the absence of the helper (parent) virus. diRNAs are referred as “interfering” because they can attenuate the symptoms caused by the helper virus, they multiply rapidly and eventually lead to slowing down of the helper virus multiplication.

Lateral flow detection A chromatography method based on lateral flow using specific antibodies applied on strips. Once the strip is submerged with the “sample” side into the sample extract, the liquid migrates upwards and initiates the antigen-antibody reaction which results in visible lines. Both test and control lines become visible with positive extracts, whereas negative samples produce the upper control line only. Lines start developing after 1–2 mn and reach maximum intensity after 10–15 mn. Dried test strips can be kept as permanent records.

Leaky scanning A mechanism used during the initiation steps of eukaryotic translation in which a “weak” initiation codon on mRNA is sometimes skipped by ribosome. During translation initiation, the small 40S ribosomal subunit “scans” or moves in a 5′ → 3′ direction along the 5′ untranslated region to locate a start codon to commence elongation. Sometimes, the scanning ribosome may encounter an “unfavorable nucleotide context” around the start codon, bypasses this start codon and begins translation at further downstream AUG start codons. This way an mRNA can encode several different proteins if the AUG are not in frame or code for proteins with different N-termini if the AUG start codons are in the same frame.

Introduction

The family *Virgaviridae* contains seven genera (*Furovirus*, *Goravirus*, *Hordeivirus*, *Pecluvirus*, *Pomovirus*, *Tobamovirus*, and *Tobravirus*) and twenty-seven species unassigned to a genus (Table 1). Virgaviruses possess positive-sense single-stranded RNA genomes encapsidated in rod-shaped particles. Virions are helically constructed from one type of coat protein (CP) with exception in members of the *Furovirus* and *Pomovirus* genera, which incorporate an additional larger minor CP into one extremity of the virus

particles. This protein is produced through translational read-through of the stop codon of CP-encoding open reading frame (ORF) and is needed for acquisition and transmission of the viruses of these two genera by plasmodiophorid protist vectors. Many virgaviruses cause economically significant diseases in vegetable, fruit, cereal and fiber crops, and in ornamental plants worldwide.

The members of *Virgaviridae* infect both monocot and dicots species and the viruses belonging to the *Furovirus*, *Pecluvirus*, *Pomovirus* and *Tobravirus* genera are soil-borne and transmitted in soil by plasmodiophorid and nematode vectors. Most Tobamoviruses are transmitted mechanically and seems not to have natural vectors. Tobacco mosaic virus (TMV; genus *Tobamovirus*) was the first virus to be discovered (in 1886) and crystallized (in 1935). The virus accumulates in extremely high concentrations in infected plants, extremely stable and is easily transmitted from plant to plant just through the contact of an infected plant with a healthy plant, e.g., through contacts facilitated by wind or air flow. This particular property of the virus, its various strains, and related viruses is used in agriculture for cross-protection.

Taxonomy, Phylogeny and Evolution

Genus demarcation criteria in the family *Virgaviridae* are based on number of genome components (mono-, bi- or tripartite), genome organization (e.g., type of the encoded movement protein, MP), mode of transmission (pollen, seed, mechanical or by vector), type of vector (plasmodiophorid or nematode), and phylogenetic relationships. Currently, virgaviruses are classified into seven genera: *Furovirus*, *Goravirus*, *Hordeivirus*, *Pecluvirus*, *Pomovirus*, *Tobamovirus*, and *Tobravirus*, briefly summarized below (Table 2).

The genus *Furovirus* comprises six recognized species: *Chinese wheat mosaic virus* (CWMV), *Japanese soil-borne wheat mosaic virus* (JSBWMV), *Oat golden stripe virus* (OGSV), *Soil-borne cereal mosaic virus* (SBCMV), *Soil-borne wheat mosaic virus* (SBWMV), and *Sorghum chlorotic spot virus* (SCSV); and one unassigned member: *French barley mosaic virus* (FBMV). The members of the genus are all bipartite soil-borne viruses transmitted by the plasmodiophorid *Polymyxa graminis* to graminaceous plants (monocots).

The genus *Goravirus* comprises two recognized species, *Drakaea virus A* (DraVA) and *Gentian ovary ringspot virus* (GORSV). The members of the genus are bipartite pollen-transmitted viruses, which infect ornamental plants (an orchid and a clustered gentian).

The genus *Hordeivirus* comprises four recognized species, *Anthoxanthum latent blanching virus* (ALBV), *Barley stripe mosaic virus* (BSMV), *Lychnis ringspot virus* (LRSV), and *Poa semilatifolia virus* (PSLV). The members of the genus are tripartite pollen- and seed-transmitted viruses, which infect monocot and dicot plants.

The genus *Pecluvirus* includes two recognized species, *Indian peanut clump virus* (IPCV) and *Peanut clump virus* (PCV). The members of the genus are bipartite soil-borne viruses transmitted naturally by *Polymyxa graminis* or by seed (in groundnuts). The viruses are also mechanically transmissible and infect monocots and dicots.

The genus *Pomovirus* comprises five recognized species and one unassigned member: *Beet soil-borne virus* (BSBV), *Beet virus Q* (BVQ), *Broad bean necrosis virus* (BBNV), *Colombian potato soil-borne virus* (CPSbV), *Potato mop-top virus* (PMTV) and *Soil-borne virus 2* (a tentative member). The members of the genus are tripartite soil-borne viruses transmitted by the plasmodiophorids to dicot plants.

The genus *Tobamovirus*, with 37 accepted species and 12 unassigned species, is the largest genus in the family *Virgaviridae*. Tobamoviruses are the only members of the family to have a non-segmented (monopartite) genome, are not vector-transmissible and when seed transmitted, the embryo is not affected. Tobamoviruses are efficiently transmitted mechanically and include TMV, the first virus to be discovered and crystallized, thus, extensively studied.

The genus *Tobravirus* comprises three recognized species, *Pea early-browning virus* (PEBV), *Pepper ringspot virus* (PRSV), and *Tobacco rattle virus* (TRV). The members of the genus are bipartite soil-borne viruses transmitted by nematodes to dicot plants.

Additionally, twenty-seven unassigned species in the family *Virgaviridae* have been recognized and include only two plant-infecting viruses: *Cucumis melo virga-like virus* and *Soil-borne barley mosaic virus*. The remaining twenty-five species were identified in metagenomics libraries and include viruses found in fungi, oomycetes, insects (mosquitoes and bumble bees), and spiders (Table 1, Table 3).

Phylogenetic analysis of the sequences of replication protein of plant-infecting *Virgaviridae* shows that virgaviruses group in clusters corresponding to the seven existing genera (Fig. 1). Similar clustering is obtained when phylogenetic analysis is performed for the sequences of movement proteins, although '30K'-type and TGB1-type MPs are analyzed separately. There are also close relationships between the cysteine-rich proteins (CRPs) encoded by the viruses of the *Furovirus*, *Hordeivirus*, *Pecluvirus*, and

Tobravirus genera, although CRP of a pomovirus, Potato mop-top virus (PMTV), do not align with them and has an entirely different sequence.

In addition, within genera, closely-related tobamoviruses are grouped according to host they infect. Among 37 tobamovirus species, there are clearly groupings of closely-related viruses infecting similar hosts, namely those infecting cruciferous plants (*Ribgrass mosaic virus*, *Turnip vein-clearing virus*, *Wasabi mottle virus*, *Youcai mosaic virus*), cucurbits (*Cucumber fruit mottle mosaic virus*, *Cucumber green mottle mosaic virus*, *Cucumber mottle virus*, *Kyuri green mottle mosaic virus*, *Zucchini green mottle mosaic virus*), and solanaceous species (*Brugmansia mild mottle virus*, *Obuda pepper virus*, *Paprika mild mottle virus*, *Pepper mild mottle virus*, *Rehmannia mosaic virus*, *Tobacco mild green mosaic virus*, TMV, *Tomato brown rugose fruit virus*, *Tomato mosaic virus*, *Tropical soda apple mosaic virus*, *Yellow tailflower mild mottle virus*). Six other genera in the family Virgaviridae do not have enough diversity to distinguish particular sub-groupings because of the limited number virus species (two to six species depending on the genus) within the genus and very narrow host range (e.g., furoviruses, which infect graminaceous plants).

Genetic diversity and evolution of virgaviruses seem to be driven by mutation, recombination and reassortment of genome components (for multipartite viruses) that significantly contribute to the emergence of new viral variants, increasing their potential of adaptation to different crop varieties, hosts and environmental conditions. These is nicely illustrated by the analysis of numerous isolates of PMTV. Phylogenetic analysis of available PMTV sequences for RNA-rep, RNA-TGB, and RNA-CP indicates that PMTV isolates around the world can be divided into two (RNA-rep and RNA-TGB) to three (RNA-CP) lineages depending on genomic segment. In all lineages, there are virus isolates from Andean region of South America demonstrating the greater variability of the virus in the Andes relative to the other parts of the world. Moreover, three of these lineages are exclusively represented by isolates from Andean region of Peru, the center of potato domestication; indicating that in Peru, PMTV has undergone great evolutionary divergence, resulting in the establishment of distinct phylogenetic clades, genotypes and genetic constellations (as PMTV has a tripartite genome).

Virion Structure

Virgaviruses have non-enveloped, rod-shaped particles with helical symmetry with a pitch of 2.3–2.5 nm and an axial canal (Fig. 2). The virions are ca. 20 nm in diameter and up to 310 nm in length. No lipids have been reported in the virions of

Fig. 1 Neighbor-joining phylogenetic tree of the codon-aligned nucleotide sequences of the replication proteins of plant-infecting viruses in the family *Virgaviridae*. The analyses were conducted in MEGA X using the Maximum Likelihood method, Tamura-Nei model and 1000 bootstrap replicates. The tree with the highest log likelihood (−185021.20) is shown. The percentage of trees in which the associated taxa clustered together is shown next to the branches. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. This analysis involved 54 nucleotide sequences. Virus abbreviations are explained in the [Table 1](#). The bar below the tree indicates nucleotide substitutions per site.

virgaviruses. The virions of all members of the family (except for members of the *Furovirus* and *Pomovirus* genera) are composed of identical CP subunits ranging in size from 17 to 24 kDa. In furoviruses and pomoviruses, the CP-RTD (coat protein – read-through domain) protein – produced by translational read-through of the CP ORF stop codon – is a minor virion component attached to one extremity of the virus particles.

Currently, high-resolution capsid structures are available for five tobamoviruses including TMV, *Cucumber green mottle mosaic virus* (CGMMV), *Tobacco mild green mosaic virus* (TMGMV), *Odontoglossum ringspot virus* (ORSV), *Ribgrass mosaic virus* (RMV), and one hordeivirus – BSMV. The capsid structures of tobamoviruses are very similar to each other, whereas compared to the tobamovirus capsids, the BSMV virions are considerably more labile and, in general, the physico-chemical properties of BSMV virions resemble to certain extent those of flexuous filamentous viruses rather than tobamoviruses.

The X-ray fiber diffraction analysis at 2.9 Å resolution and cryoelectron microscopy (EM) at 4.6 Å resolution has shown that the virions of TMV are built from one distinct conformation of a single CP. The inter-subunit contacts in tobamovirus virions include strong lateral and axial electrostatic interactions, and the hydrophobic girdle formed by lateral hydrophobic contacts between adjacent subunits at a high virion radius (**Fig. 2(B)**). These types of interactions are believed to predispose the exceptionally high stability of tobamovirus virions. Surprisingly, Cryo-EM structure at 4.1 Å resolution has shown that the capsids of the hordeivirus BSMV are built from two

distinct conformations of a single CP, and that these conformational differences facilitate the formation two structurally distinct forms of BSMV virions, 'wide' and 'narrow' virions with diameters of 224 Å and 216 Å, respectively (Fig. 2(C)). Wide virions incorporate 111 subunits per helix period, while narrow virions have 106 subunits. Both virion forms co-exist in the populations of BSMV particles. The functional differences between the two forms of BSMV virions are not known. Structural data show that the narrow BSMV virions are more stable than the wide virions because of the stronger CP contacts with RNA and additional contacts between CP subunits.

Each virion of virgaviruses contains a single copy of ssRNA. Thus, for viruses with bipartite or tripartite genomes, two or three virions, respectively, containing different genomic components are required for establishing infection. The differences in virion size are particularly evident for bipartite tobamoviruses as they have virus particles of two predominant lengths, (L) 180–215 nm and (S) ranging from 46 to 115 nm, depending on the isolate (Fig. 2(D)). RNA1 is encapsidated into the L-particles, whereas the S-particles contain RNA2. Defective genome components (defective interfering RNA, diRNA) associated with pomoviruses have also been found to be encapsidated.

Genome Organization

The 5' untranslated region (UTR) of many virgaviruses contain the starting sequence GU(A)_{1–4}(U)_n. The RNAs are probably capped at the 5' end since the viral replicases contains methyl-transferase motifs associated with capping activity. The terminal ca. 80–240 nt of the 3' UTR can be folded into a tRNA-like structure that contains an anticodon for valine (furo-, peclu- and pomoviruses), tyrosine (hordeiviruses) or histidine (tobamoviruses; Table 2). For some hordei-, pomo- and tobamovirus the genomic RNAs were shown to be amino-acylated (tyrosylated, valylated and histidinated, respectively) experimentally. Different from other virgaviruses, tRNA-like structure of a pomovirus CPSPV contains an anticodone for leucine. Although genomic RNAs of virgaviruses are not polyadenylated, hordeiviruses BSMV and LRSV contain internal poly(A) tracts, which precede the tRNA-like structure.

Genomic RNAs of virgaviruses typically have three to seven ORFs. The genome expression strategy is based on: (i) read-through of leaky stop codons - e.g., expression of replicases and CP-RTD proteins; (ii) expression of the downstream ORFs via the synthesis of a nested set of 3' co-terminal sub-genomic mRNAs (sgRNAs) - e.g., expression of MPs, cysteine-rich proteins and CP (in tobamoviruses); and (iii) leaky scanning - e.g., expression of TGB2/TGB3 (gora-, hordei- peclu- and pomoviruses), and CP/P39 (pecluviruses).

The genome organization is conserved among species within the same genus, but not in the family in general (Fig. 3). However, the 5' proximal ORF of all largest genomic components invariably encodes the replication-associated proteins (replicases) with conserved domains for a methyltransferase (MET), a helicase (HEL), and an RNA-dependent RNA polymerase (RdRp), a domain arrangement typical of alpha-like viruses. The replicases are translated directly from the genomic RNAs. In viruses of all genera except the genus *Hordeivirus*, RdRp is expressed as the C-terminal part of the replicase by read-through of a leaky stop codon (Fig. 3). In the genus *Hordeivirus* RdRp is translated from a smaller genomic component RNA_γ. Other viral proteins are translated either directly from the smaller genomic RNAs or from sgRNAs, some of which may be bicistronic and are translated by leaky scanning mechanism. In viruses of all genera except the genus *Tobamovirus*, CP is translated directly from the smaller genomic RNAs. In the genus *Tobamovirus*, CP is expressed via formation of sgRNA.

The viruses of the genera *Furovirus*, *Tobamovirus* and *Tobravirus* encode a single MP of the "30K" superfamily, whereas in other genera there is a triple gene block (TGB) of MPs (Fig. 3; Table 2). The coordinated expression and action of the proteins encoded by TGB mediates virus movement in the infected plant.

The viruses of the genera *Furovirus*, *Goravirus*, *Hordeivirus*, *Pecluvirus*, *Tobravirus*, and PMTV, but not other pomoviruses, encode cysteine-rich proteins (CRPs, Fig. 3). These CRPs, except the one encoded by PMTV, share well-conserved C3H1-type (C, cysteine residue; H, histidine residue) zinc-finger domain. CRP encoded by PMTV has a SWIM-type zinc-finger characterized by a consensus sequence CxC_nCxC, in which C stands for cysteine residue and x refers to any aa residue. CRPs of virgaviruses are expressed from sgRNAs, function as suppressors of RNA silencing and are essential for virus infectivity or/and efficient virus accumulation in the infected plants. However, in tobamoviruses soluble replication proteins (not associated with membranes) are involved in suppression of RNA silencing, but do not participate in RNA replication (Fig. 3).

Replication

After virus entry, the genomic RNA is translated to produce replication proteins. Replication occurs on virus-induced spherular invaginations of cytoplasmic membranes similar to RNA replication-linked spherules induced by many positive-sense RNA viruses. Full length negative-sense strand synthesis and subsequent positive-sense strand synthesis takes place inside the spherules. Replication proteins bind to the 3' terminal tRNA-like structure to initiate negative-strand RNA synthesis. In the spherule, the interior space of which is connected with the cytoplasm via a thin neck, viral positive-sense RNA strands are synthesized using negative-sense strand as a template. Subsequently, multiple copies of positive-sense RNA strands and sgRNAs are released into the cytoplasm through the neck. The replication proteins of virgaviruses, as those of other positive-sense RNA viruses, are tightly associated with membranes. Attempts to purify viral replicases from infected plants cells and to solubilize them resulted in drastic changes in their properties.

sgRNAs are transcribed from negative-sense RNA through recognition of sub-genomic promoters by replication proteins. For some virgaviruses, comparison of the sequences of sub-genomic promoters reveals conservative consensus motifs.

The membrane used to form the replication compartments varies and depends on the virus, for example, TMV, ToMV and Youcai mosaic virus (and probably other tobamoviruses) may forms active replication machinery on the vacuolar and endoplasmic

Fig. 3 Diagram showing the genome organization of representative members of the seven genera in the family *Virgaviridae*. ORFs are color-coded according to the function of their protein products: replication proteins are in pink with the methyltransferase (M), helicase (H), and RdRp (P) domains; coat proteins are in green; '30K'-type movement proteins are in blue; triple gene block movement proteins are in light brown; cysteine-rich proteins are in yellow; and other ORFs are in white. Positions of 'leaky' stop codons are shown by black diamonds and tRNA-like structures with clover leaves. Val/Tyr/Leu/His/?/-: amino-acylation of tRNA-like structures, respectively. Brackets indicate ORFs that are missing from some strains.

reticulum (ER) membranes, whereas BSMV (a hordeivirus) uses the outer membranes of chloroplasts for replication. Evidence suggests that PMTV TGB2, a two-pass transmembrane protein, targets membranes of chloroplasts to establish the virus replication compartment in there. TRV viral factories are enriched in mitochondria-derived membranes.

Tobamovirus replication proteins co-translationally bind to AC-rich region of the 5' UTR of the genomic RNA to form so-called premembrane targeting complex. This represents the first step in tobamovirus RNA replication. Host factors involved in the tobamovirus replication were identified by forward genetic approaches and co-immunoprecipitation, and include TOM1, TOM2A, TOM2B, and ARL8 proteins. Tobamovirus replication complexes are anchored into membranes through interaction of the helicase domain of the replicase with TOM1, a seven-pass transmembrane protein. In turn, TOM2A, a four-pass transmembrane protein, interacts with TOM1. ARL8, an ADP-ribosylation factor-like small GTP-binding protein, interacts with both TOM1 and an N-terminal alpha-helix of the helicase domain of the replication proteins. The replication proteins first bind to membranes and then interact and form a complex with TOM1, TOM2A, and ARL8. Interaction with membranes and TOM1 and ARL8 proteins activates the RNA 5' capping activity of the 126 kDa protein (a tobamovirus protein harboring methyl-transferase and helicase domains). The timing and the trigger of the activation of the tobamovirus RdRp activity and the mechanism of its template strand switch are unknown so far.

When significant amount of positive-sense genomic RNA builds up in the infected cell, progeny rod-shaped virions are assembled in the cytoplasm. Mature virions accumulate in the infected cells and might be acquired by the vectors.

Infectious Cycle

Infection with virgaviruses is initiated when a virus is delivered into the plant cell. Depending on the virus genus this is achieved either by rub-inoculation (mechanical transmission) – the mode of virus transmission possible for most virgaviruses and the only way of transmission for the viruses of the genus *Tobamovirus* – or by the vector (plasmodiophorid or nematode). In the plant cell, ssRNA of virgaviruses gets uncoated from virions and is translated to produce replication-associated proteins. The replication complex then initiates rearrangement and remodeling of host intracellular membranes to establish viral replication organelles or virus factories. Such compartments secure efficient RNA replication and synthesis of sgRNA, and protect viral RNA from nucleases and pattern recognition receptors that upon activation can trigger host innate immunity responses, *e.g.*, in response to dsRNA accumulation. Later in infection, viral MPs are expressed from sgRNA (for most virgaviruses). MPs facilitate cell-to-cell and systemic movement of the virus in the infected plant. Some members of the family *Virgaviridae* require expression of CP for systemic movement. When sufficient amount of CP is expressed, ssRNA can then be encapsidated by CP into virions, which become available for vector acquisition and subsequent transmission. Virions of virgaviruses can aggregate forming inclusion bodies, virion arrays and other paracrystalline structures in the plant cell.

An important step of the life cycle of the soil-borne viruses of the *Furovirus*, *Pecluvirus* and *Pomovirus* genera is the transmission between plants by a plasmodiophorid vector. The dormant resting spores of plasmodiophorids carrying a virgavirus can persist in soil for more than fifteen years. Under high levels of soil moisture and cool temperatures, the resting spores germinate and release primary virus-carrying zoospores that attach to and penetrate root tissue of the host, mostly root hairs. Zoospores are responsible for transmission of virgaviruses to host plants and the viruses reside inside the zoospores. After penetration, the zoospore develops into a multinucleate plasmodium, which after growth, increasing in size and proliferating into segments forms zoosporangia, each harboring numerous secondary zoospores that can infect new roots. Although the exact mechanism of the virus acquisition by plasmodiophorids is not known, it has been speculated that it might occur at the plasmodium stage, probably, through fusion of membranes induced by CP-RTD proteins located at one extremity of virus particles. Intriguingly, CP-RTD proteins of virgaviruses have two transmembrane hydrophobic segments - the arrangement resembles membrane fusion proteins of enveloped animal viruses. Deletions in CP-RTD proteins resulting in the loss of at least one transmembrane segment prevent transmission of the virus by the vector. Although, whether virgaviruses replicate in the plasmodiophorid vector is still unknown.

Diagnosis

The members of the family *Virgaviridae* incite various leaf symptoms including yellow mosaic, ring spots, stripes, streaks, necrotic spots, leaf malformations *etc.* However, identification of the virgaviruses based these symptoms might be misleading because similar symptoms may be induced by other viruses. Thus, diagnosis based on appearance of symptoms is not sufficient and specific diagnostic tests must be employed to confirm virgavirus infection.

Brown arcs and rings in the potato tuber flesh are typical symptoms of ‘spraing’, a Scottish word referring to a dark, variegated streak or stripe. ‘Spraing’ can be caused by PMTV (genus *Pomovirus*) or TRV (genus *Tobravirus*). Reliable methods are needed to determine whether symptoms are caused by PMTV or TRV.

Several techniques have been developed and successfully used to detect the presence of virgaviruses, including serological assays, nucleic-acid-based methodologies, and next generation sequencing (NGS). A number of serological diagnostic techniques such as an enzyme-linked immunosorbent assay (ELISA) have been developed for fast, simple, cost-effective and high-throughput testing. Serological reagents are available for many viruses in the family *Virgaviridae*, including reagents for ELISA (*e.g.*, for PMTV, TMV, ToMV, TRV *etc.*) and strips for lateral flow detection (*e.g.*, for detection of TMV and ToMV). Lateral flow assays provide very rapid diagnosis within minutes, are easily portable and highly robust, and have been adopted by agronomists and farm advisors as means of quickly confirming the presence of a specific virgavirus within a crop in the field.

Nucleic acid-based diagnostic methods have become increasingly popular for detection and characterization of virgaviruses. Such techniques include various modifications of reverse transcription (RT) polymerase chain reaction (PCR): classical RT-PCR, immunocapture-RT-PCR, quantitative real-time RT-PCR (RT-qPCR), loop-mediated isothermal amplification, and oligonucleotide microarrays. These assays are often more robust and sensitive than serological assays. Recently, NGS, including RNA-seq and sequencing of small RNAs, has become increasingly accessible for discovery of new viruses, including virgaviruses. These holistic approaches provide an unbiased identification and characterization of a whole virome in a sample without any prior knowledge of the pathogens present.

Pathogenicity

Despite significant advances in studies of the mechanisms of pathogenicity (the ability of a virus to cause disease on a particular host), the information about how virgaviruses cause disease in their host is surprisingly scant. Pathogenicity determinants include

CRPs encoded by the viruses of the *Furovirus*, *Goravirus*, *Hordeivirus*, *Pecluvirus*, *Pomovirus*, and *Tobravirus* genera. For example, natural variants of CRPs from various BSMV strains have a number of specific effects on the virus pathogenesis including the ability of certain strains to establish systemic infection in the absence of the CRP expression. However, the failure of certain strains to establish systemic infection can be reversed by mutations (deletions of N-terminal duplication of the polymerase domain) that increase the abundance of viral polymerase, and, thus, increase the virus replication rate.

The function of CP in pathogenicity and symptom modulation was shown for pomo- and tobamoviruses. PMTV causes symptomless infections in the absence of the CP expression. On the contrary, TMV mutants defective in CP expression still display mild mosaic symptoms. However, the appearance of bright chlorosis symptoms is linked to specific aa substitutions within the TMV CP and results from disruption of chloroplast development and homeostasis. TMV CP associates with and disrupts photosystem II complexes in the thylakoid membranes of chloroplasts.

Epidemiology and Control

The viruses in the genera *Furovirus*, *Pecluvirus* and *Pomovirus* are transmitted in soil by plasmodiophorid vectors (Table 2). *Polymyxa graminis* and *Spongospora subterranea* are known vectors of the viruses in these three genera. Viruses transmitted by plasmodiophorids reside inside the zoospores or dormant resting spores of their vector and, thus, well protected from the environment. The virus-carrying resting spores also remain viruliferous for many years. These features make eradication of the diseases caused by plasmodiophorid-transmitted viruses very difficult, and infestations are usually permanent, once the virus is introduced into the field.

The viruses in the genus *Tobravirus* are transmitted in soil by nematode vectors. In general, management of nematodes is difficult. The existing infestations can be reduced through fallowing, crop rotation, and soil solarization.

Transmission through seed and pollen has been documented for the viruses in the genera *Goravirus* and *Hordeivirus*. No vector is known for viruses in the genus *Tobamovirus*. Tobamoviruses are readily transmittable by mechanical inoculation. Most of the viruses in the family *Virgaviridae* are mechanically transmittable in lab conditions.

The family *Virgaviridae* includes viruses (BSMV, PCV, PMTV, TMV, ToMV, TRV etc.) that are responsible for significant quantitative and qualitative yield losses in various crops, whereas the economic significance of other family members is limited, not well studied or not important. Many factors affect the occurrence and incidence of diseases caused by virgaviruses. Application of integrated pest management (IPM) strategies would be beneficial to control of virgavirus-induced diseases as IPM takes into account all those factors. For plasmodiophorid- and nematode-transmitted viruses disease management is mainly preventive through the use of virus-free seed material (e.g., virus-free seed tubers) and non-infested fields. Cross-protection with mild viral strains has been used successfully to control some virus diseases caused by tobamoviruses (e.g., TMV and ToMV). Mild strain protection of tomato against ToMV is probably one of the most successful applications of cross-protection. It is successfully and routinely used in Europe, Canada, New Zealand, Israel, and Japan.

One of the best ways to manage virgaviruses is to use varieties that are resistant to the viruses. Four dominant genes conferring resistance to virgaviruses have been cloned and sequenced. Three of these genes encode members of the nucleotide-binding site-leucine-rich repeat (NBS-LRR) class of R proteins, whereas *Tm-1* gene encodes a TIM barrel structure protein. The R proteins localize to the cytoplasm consistent with the lifecycle of virgaviruses. ToMV was once one of the most important pathogens of tomato crop, but effective control has been established using resistant cultivars with three ToMV resistance genes: *Tm-2/Tm-2²* and *Tm-1*. *N*-gene-mediated resistance to TMV is another example of solving a practical problem and putting disease resistance in the field.

Unassigned Virgaviruses

Recent advances in low-cost high-throughput NGS led to identification of a number of virga-like viruses in metagenomics data generated for invertebrates, fungi and oomycetes (Table 3). Most of these viruses seem to be monopartite with genomes ranging 6.8–11.9 kb. However, one cannot exclude the possibility that some of the viruses in this group might have multipartite genomes as currently only partial sequences are available.

Glossary

Catalytic RNA RNA molecules that are able to catalyze, in a protein-free medium, specific reactions involving the formation or breakage of covalent bonds. In nature, these reactions are usually transesterifications (self-cleavage and ligation) affecting the catalytic RNA itself.

Hammerhead structure The conserved secondary/tertiary structure shared by the smallest class of natural ribozymes. Most were initially found in one or both strands of certain

viroid and viroid-like satellite RNAs where they mediate self-cleavage of multimeric intermediates arising from replication through a rolling-circle mechanism. More recently, the hammerhead ribozyme motif has been reported along the tree of life.

Ribozyme RNA motif responsible for the catalytic activity of certain RNA molecules. In nature, they are found embedded within catalytic RNAs.

Taxonomy

According with the presence of conserved sequence/structure motifs, and mode of replication and subcellular accumulation sites, viroids are allocated to the family *Pospiviroidae* (composed of genera *Pospiviroid*, *Hostuviroid*, *Cocadviroid*, *Apsacaviroid* and *Coleviroid*), type species *Potato spindle tuber viroid*, and family *Avsunviroidae* (composed of genera *Avsunviroid*, *Pelamoviroid* and *Elaviroid*), type species *Avocado sunblotch viroid*.

Introduction

Viroids are the smallest known agents of infectious disease – small (246–401 nt), highly structured, single-stranded, circular RNAs – that lack detectable messenger RNA activity. Whereas viruses have been described as “obligate parasites of the cell’s translational system” and supply some or most of the genetic information required for their replication and movement, viroids can be regarded as “obligate parasites of the cell’s transcriptional machinery”. Thus far, viroids are known to infect only plants.

The first viroid disease to be studied by plant pathologists was potato spindle tuber. In 1923, its infectious nature and ability to spread in the field led Schultz and Folsom to group potato spindle tuber disease with several other “degeneration diseases” of potatoes. Nearly 50 years were to elapse before Diener’s 1971 demonstration that the molecular properties of its causal agent, Potato spindle tuber viroid (PSTVd), were fundamentally different than those of conventional plant viruses.

Genome Structure

Efforts to understand how viroids replicate and cause disease without the assistance of any viroid-encoded polypeptides has prompted detailed analysis of their structure. Viroids possess rather unusual properties for single-stranded RNAs (*e.g.*, a pronounced resistance to digestion by ribonucleases and a highly cooperative thermal denaturation profile), leading to an early realization that they might have an unusual higher-order structure.

To date, the complete sequences of 32 distinct viroid species plus a large number of sequence variants have been determined (Table 1). All are single-stranded circular RNAs with unmodified nucleotides. Theoretical calculations and physicochemical studies indicate that PSTVd and related viroids assume a highly base-paired, rod-like conformation *in vitro* (Fig. 1), with recent data supporting a similar secondary structure *in vivo* for PSTVd and Avocado sunblotch viroid (ASBVd), which appear to accumulate *in planta* as free RNAs unprotected by tightly bound proteins. Pair-wise sequence comparisons suggest that the series of short double helices and small internal loops that comprise this so-called “native” structure are organized into five domains whose boundaries are defined by sharp changes in sequence identity.

The “central domain” is the most highly conserved viroid domain and contains the site where multimeric PSTVd RNAs are cleaved and ligated to form circular progeny. The “pathogenicity domain” contains one or more structural elements that modulate symptom expression, and the relatively small “variable domain” exhibits the greatest sequence variability between otherwise closely-related viroids. The two “terminal domains” appear to play an important role in viroid replication and evolution. Although these five domains were first identified in PSTVd, Apple scar skin viroid (ASSVd) and related viroids also contain a similar domain arrangement. Certain viroids, such as Columnea latent viroid (CLVd), Australian grapevine viroid (AGVd) and *Coleus blumei* viroid 2 (CbVd 2), appear to be “mosaic molecules” formed by exchange of domains between two or more viroids infecting the same cell. RNA rearrangement/

Table 1 Classification of viroids of known nucleotide sequence

Family ^a	Genus ^a	Name	Abbreviation	Nucleotides ^b
<i>Pospiviroidae</i>	<i>Pospiviroid</i>	<i>Chrysanthemum stunt viroid</i>	CSVd	354–356
		<i>Citrus exocortis viroid</i>	CEVd	368–375 (463–467)

	<i>Elaviroid</i>	<i>Eggplant latent viroid</i>	ELVd	332–335

^aClassification follows scheme proposed by Owens *et al.* 2012 (see Virus Taxonomy, IX Report of the International Committee on Taxonomy of Viruses) with minor modifications. Whether Apple fruit crinkle viroid, Apple hammerhead viroid, Coleus blumei viroids 4, 5 and 6, Grapevine hammerhead viroid-like RNA, Grapevine latent viroid, Grapevine yellow speckle viroid 3, Persimmon latent viroid, Persimmon viroid 2, and Portulaca latent viroid should be considered variants or new viroid species of a different genus is pending.

^bSizes of variants containing insertions or deletions arising *in vivo* are shown in parentheses.

^cIncludes Cucumber pale fruit viroid, Citrus cachexia viroid, Peach dapple viroid, and Plum dapple viroid.

^dIncludes Pear rusty skin viroid and Dapple apple viroid.

^eFormerly termed Grapevine viroid 1B.

recombination can also occur within individual domains, leading, in Coconut cadang-cadang viroid (CCCVd) and Citrus exocortis viroid (CEVd), to duplications of the right terminal domain plus part of the variable domain. This domain model is not shared by ASBVd and related viroids.

Much less is known about the tertiary structure of viroids, especially *in vivo*. UV-induced cross-linking of two nucleotides within a loop E motif in the central domain of PSTVd provided the first definitive evidence for such tertiary interactions. Similar UV-sensitive structural elements have also been discovered in a number of other RNAs including 5S eukaryotic rRNA, adenovirus VAI RNA, and the viroid-like domain of the hepatitis delta virus genome. Loop E forms during the conversion of multimeric PSTVd RNAs into monomers. The ability of ASBVd-related RNAs to undergo spontaneous self-cleavage mediated by hammerhead ribozymes, as well as the presence of kissing-loop interactions critical for infectivity in some other members of the *Avsunviroidae* (Fig. 1), provide additional evidence for the functional importance of viroid tertiary structure.

Classification

Based upon differences in their structural and functional properties, viroids are assigned to one of two taxonomic families (Table 1). Members of the family *Pospiviroidae* (type species PSTVd) fold into a rod-like secondary structure with five structural-

Fig. 1 (a) The rod-like secondary structure of PSTVd (intermediate strain) showing the five domains characteristic of members of the family *Pospiviroidae*: the Terminal Left (T_L), Pathogenicity (P), Central (C), Variable (V), and Terminal Right (T_R). The Central Conserved Region (CCR) is located within the C domain and contains a UV-sensitive loop E motif with non-canonical base-pairs (denoted by circles). The T_L domains of genera *Pospiviroidae* and *Apscaviroid* contain a Terminal Conserved Region (TCR), while those of genera *Hostuviroid* and *Cocadviroid* contain a Terminal Conserved Hairpin (not shown). The T_R may also contain 1–2 copies of a protein-binding RY motif. (b) The branched secondary structure of PLMVd (reference variant). Plus and minus self-cleavage domains are indicated by flags, nucleotides conserved in most natural hammerhead structures by bars, and the self-cleavage sites by arrows. Black and white symbols refer to plus and minus polarities, respectively. Nucleotides involved in a kissing-loop interaction are indicated by broken lines. Redrawn with modifications from Gross, H.J., Domdey, H., Lossow, C., *et al.*, 1978. Nucleotide sequence and secondary structure of potato spindle tuber viroid. *Nature* 273, 203–208. Hernández, C., Flores, R., 1992. Plus and minus RNAs of peach latent mosaic viroid self-cleave in vitro via hammerhead structures. *Proceedings of the National Academy of Sciences of the United States of America* 89, 3711–3715. Bussiére, F., Ouellet, J., Côté, F., Lévesque, D., Perreault, J.P., 2000. Mapping in solution shows the peach latent mosaic viroid to possess a new pseudoknot in a complex, branched secondary structure. *Journal of Virology* 74, 2647–2654.

functional domains and several conserved motifs. Most members of the family *Avsunviroidae* (type species ASBVd), in contrast, appear to adopt a branched conformation, and multimeric RNAs of all family species behave as catalytic RNAs and undergo spontaneous self-cleavage (Fig. 1). Differences in their sites of replication also support this classification scheme; *i.e.*, PSTVd and ASBVd replicate in the nucleus and plastids (mostly chloroplasts), respectively, and the same appears to occur for other family species. Each family is subdivided into genera according to certain demarcating criteria. Groups of sequence variants that show > 90% sequence identity in pair-wise comparisons and share some common biological property are arbitrarily defined as viroid species. *In vivo*, each viroid species is actually a “quasi-species”; *i.e.*, a collection of closely-related sequence variants subject to a continuous process of mutation, competition, and selection. Phylogenetic evidence supports an evolutionary link between viroids and other viroid-like subviral RNAs (Fig. 2).

Host Range and Transmission

All viroids are mechanically transmissible, and most are naturally transmitted from plant to plant by man and his tools. Individual viroids vary greatly in their ability to infect different plant species. PSTVd can replicate in about 160 primarily solanaceous hosts, while only two members of the family *Lauraceae* are known to support ASBVd replication. Hop stunt viroid (HSVd) has a particularly wide host range that includes herbaceous species as well as woody perennials. Many natural hosts are either vegetatively propagated or crops that are subjected to repeated grafting or pruning operations. PSTVd, ASBVd, and *Coleus blumei* viroid 1 (CbVd 1) are vertically transmitted through pollen and/or true seed, but the significance of this mode of transmission in their natural spread is unclear. PSTVd can be encapsidated by the coat protein of Potato leafroll virus (PLRV, a luteovirus) as well as Velvet tobacco mottle virus (VTMoV, a sobemovirus), and epidemiological surveys suggest that PLRV facilitates viroid spread under field conditions.

Commonly used techniques for the experimental transmission of viroids include the standard leaf abrasion methods developed for conventional viruses, “razor slashing” methods in which phloem tissue in the stem or petiole is inoculated via cuts made with a razor blade previously dipped into the inoculum, and, in the case of CCCVd, high-pressure injection into folded apical leaves. Viroids can also be transmitted by either plant transformation or “agro-inoculation” during which a modified *Agrobacterium tumefaciens* Ti plasmid is used to introduce full-length viroid-complementary DNA into the potential host cell. Either technique can overcome the marked resistance of some hosts to mechanical inoculation. Identification of the molecular mechanism(s) that determine viroid host range remains an important research goal.

Symptomatology

Viroids and conventional plant viruses induce a very similar range of macroscopic symptoms. Symptom expression is usually optimal at the same relatively high temperatures (30–33°C) that promote viroid replication/accumulation. Stunting and leaf epinasty (a downward curling of the leaf lamina resulting from unbalanced growth within the various cell layers) are considered the classic symptoms of viroid infection. Other commonly observed symptoms include vein clearing, veinal discoloration or necrosis, and the appearance of localized chlorotic/necrotic spots or mottling in the foliage. Symptoms may also be expressed in flowers and bark, and fruits or tubers from viroid-infected plants may be abnormally shaped or discolored. Viroid infection of certain citrus rootstock/scion combinations may result in tree dwarfing (Fig. 3). Viroid infections are often latent and rarely kill the host.

Viroid infections are also accompanied by a number of cytopathic effects – chloroplast and cell wall abnormalities, the formation of membranous structures in the cytoplasm, and the accumulation of electron-dense deposits in both chloroplasts and cytoplasm. Metabolic changes include dramatic alterations in growth regulator levels.

Geographic Distribution

Although PSTVd, CEVd, HSVd and ASBVd are widely distributed throughout the world, other viroids have never been detected outside the areas where they were first reported. Several factors may contribute to this variation in distribution pattern. Among the crops most affected by viroid diseases are a number of valuable woody perennials such as grapes, citrus, various pome and stone fruits, and hops. Propagation and distribution of improved cultivars is highly commercialized, with the result that many cultivars are now grown worldwide. The international exchange of plant germplasm also continues to increase at a rapid rate. In both instances, the large number of latent (asymptomatic) hosts facilitates viroid spread.

Epidemiology and Control

Viroid diseases represent a potential threat to agriculture, and several are of considerable economic importance. Ready transmission of PSTVd by vegetative propagation, foliar contact, and true seed or pollen continues to pose a serious threat to potato germplasm and breeding programs. Coconut cadang-cadang has killed over 30 million palm trees in the Philippines since it was first recognized in the early 1930s. While many viroids were first detected in ornamental or crop plants, most viroid diseases are

Fig. 2 Neighbor-joining phylogenetic tree obtained from an alignment manually adjusted to take into account local similarities, insertions/deletions, and duplications/rearrangements described in the literature for viroid and viroid-like satellite RNAs. Bootstrap values were based on 1000 random replicates (only values > 70% are reported). Viroid abbreviations as in [Table 1](#). Viroid-like satellite RNAs: sLTSV (lucerne transient streak virus); sRYMV (rice yellow mottle virus); sSCMoV (subterranean clover mottle virus); sSNMoV (*Solanum nodiflorum* mottle virus); sVTMoV (velvet tobacco mottle virus); sTRSV (tobacco ringspot virus); sArMV (*Arabidopsis* mosaic virus); sChYMV (chicory yellow mottle virus); sCYDV-RPV (cereal yellow dwarf virus-RPV). Adapted from Elena, S.F., Dopazo, J., de la Peña, M., *et al.*, 2001. Phylogenetic analysis of viroid and viroid-like satellite RNAs from plants: A reassessment. *Journal of Molecular Evolution* 53, 155–159, with permission.

thought to result from chance transfer from endemically-infected wild species to susceptible cultivars ([Diener, 1979](#)). Several lines of circumstantial evidence are consistent with this hypothesis:

- (1) The experimental host ranges of several viroids include many wild species, and these wild species often tolerate viroid replication without the appearance of recognizable disease symptoms.
- (2) Although co-evolution of host and pathogen is often accompanied by appearance of gene-for-gene vertical resistance, no useful sources of resistance to PSTVd infection have been identified in the cultivated potato.
- (3) Viroids and/or viroid-related RNAs closely related to Tomato planta macho viroid (TPMVd) and CCCVd have been detected in weeds and other wild vegetation growing near fields containing viroid-infected plants.

Fig. 3 (a) Symptoms of PSTVd infection in Rutgers tomato approximately four weeks after inoculation of cotyledons with PSTVd strains causing mild, intermediate, and severe symptoms. (b) Symptoms of ASBVd infection in avocado fruits and leaves. (c) CDVd-induced dwarfing of citrus growing on susceptible rootstocks. All trees in the block were graft-inoculated with CDVd shortly after transfer to the field; only one tree (right foreground) escaped infection. Note difference in height.

Growers and plant pathologists are unlikely to have simply overlooked diseases with symptoms as severe as those of chrysanthemum stunt or cucumber pale fruit, two diseases first reported after World War II. Large-scale monoculture of genetically identical crops and the commercial propagation/distribution of many cultivars are two comparatively modern developments which would facilitate the development of serious disease problems following the chance transfer of viroids from wild hosts to cultivated plants. Viroid diseases may also arise by transfer between cultivated crop species. For example, pears provide a latent reservoir for ASSVd; likewise, while HSVd infections of grapes are often symptomless, this viroid causes severe disease in hops. In both instances, the two crops are often grown in close proximity. In other instances, however, such proximity does not apparently exist, as in a hop disease induced by Citrus bark cracking viroid (CBCVd) recently reported in Slovenia, where citrus is not grown.

Because no useful sources of natural resistance to viroid diseases are known, diagnostic tests continue to play a key role in efforts to control these diseases. Since viroids lack a protein capsid, the antibody-based techniques used to detect many plant viruses are not applicable. Tests based upon their unique molecular properties have largely supplanted biological assays, which require extended periods (weeks to years) of time for completion and have difficulties in detecting mild or latent strains. Bioassays remain indispensable for assessing the autonomous replication of a candidate viroid-like RNA and, eventually, for fulfilling Koch's postulates. Several rapid (1–2 day) protocols involving polyacrylamide gel electrophoresis under denaturing conditions take advantage of the circular nature of viroids. Using these protocols, nanogram amounts of viroid can be unambiguously detected without the use of radioactive isotopes. In recent years, diagnostic procedures based upon nucleic acid hybridization or the polymerase chain reaction (PCR) have become widely used. The simplest methods involve the hybridization of a non-radioactively labeled viroid-complementary DNA or RNA probe to viroid samples that have been bound to a solid support followed by colorimetric or chemiluminescent detection of the resulting DNA-RNA or RNA-RNA hybrids. Such conventional "dot blot" assays can detect picogram amounts of viroids using clarified plant sap or tissue prints rather than purified nucleic acid as the viroid source. PCR-based protocols are finding increasing acceptance in those cases where either this level of sensitivity is not reached or a number of closely-related viroids are present in the same sample.

Molecular Biology

Although devoid of messenger RNA activity, viroids replicate autonomously and cause disease in a wide variety of plants. Much has been learned about the molecular biology of viroids and viroid-host interaction over the past 40 years, but the precise nature of the molecular signals involved remains elusive. A series of questions first posed by Diener summarizes the many gaps in our current understanding of the biological properties of these unusual molecules:

- (1) What molecular signals do viroids possess (and cellular RNAs evidently lack) that induce certain DNA-dependent RNA polymerases to accept them as templates for the synthesis of complementary RNA molecules?
- (2) What are the molecular mechanisms responsible for viroid replication? Are these mechanisms operative in uninfected cells? If so, what are their functions?
- (3) How do viroids induce disease? In the absence of viroid-specified proteins, disease must arise from direct interaction(s) of viroids (or viroid-derived RNA molecules) with host cell constituents. Infections by PSTVd or ASBVd induces RNA silencing (see below), but does this mechanism mediate pathogenesis for all viroids?
- (4) What determines viroid host range? Are viroids restricted to higher plants, or do they have counterparts in animals?
- (5) How did viroids originate?

Replication

A variety of multimeric plus and minus strand RNAs have been detected by nucleic acid hybridization in viroid-infected tissues. Based on their analysis, viroid replication has been proposed to proceed via a "rolling circle" mechanism that involves reiterative transcription of the incoming plus circular RNA to produce a minus strand RNA template. ASBVd and related viroids utilize a symmetric replication cycle in which the multimeric minus strand is cleaved to unit-length molecules and circularized before serving as template for the synthesis of multimeric plus strands. PSTVd and related viroids utilize an asymmetric cycle in which the multimeric minus strand is directly transcribed into multimeric plus strands. In both cases, the multimeric plus strands are cleaved to unit-length molecules and circularized (Fig. 4).

A diversity of host-encoded enzymes have been implicated in viroid replication. Low concentrations of α -amanitin specifically inhibit the synthesis of both PSTVd plus and minus strands in nuclei isolated from infected tomato, strongly suggesting the involvement of DNA-dependent RNA polymerase II, transcribing an RNA template, in the replication of PSTVd and related viroids. In nuclear extracts, synthesis of the PSTVd minus strand by RNA polymerase II starts in the left terminal loop of the plus strand template; furthermore, incubation of active replication complexes containing CEVd with a monoclonal antibody directed against the carboxy-terminal domain of RNA polymerase II results in the immunoprecipitation of both CEVd plus and minus strand RNAs. Mature PSTVd plus strands accumulate in the nucleolus and the nucleoplasm, while *in situ* hybridization indicates that minus strand RNAs are confined to the nucleoplasm. After some debate, the identity of the polymerase(s) responsible for replication of members of the family *Avsunviroidae* in the chloroplast appears now more certain. ASBVd synthesis is resistant to

Fig. 4 Asymmetric and symmetric variants of the rolling-circle mechanism proposed for replication of members of the families *Pospiviroidae* and *Avsunviroidae*, respectively. Orange and blue colors refer to plus and minus polarities, respectively, with cleavage sites denoted by arrowheads. The enzymes and ribozymes that presumably catalyze the replication steps are indicated. Notice that RNA polymerase II (and NEP) is redirected to transcribe RNA templates, and DNA ligase 1 to circularize RNA substrates. Abbreviations: HHRz, hammerhead ribozyme; NEP, nuclear-encoded polymerase. Adapted from Flores, R., Gago-Zachert, S., Serra, P., Sanjuán, R., Elena, S.F., 2014. Viroids: survivors from the RNA world? *Annual Review of Microbiology* 68, 395–414, with permission.

tagetitoxin, strongly indicating the involvement of a nuclear-encoded chloroplastic DNA-dependent RNA polymerase (NEP) again transcribing an RNA template. Initiation sites for both ASBVd plus and minus strand synthesis have been mapped to the AU-rich terminal loops of their respective native structures. Furthermore, Peach latent mosaic viroid (PLMVd) replicates actively in albino leaf areas (where only NEP is active), with the initiation sites of plus and minus strands mapping at a short double-stranded RNA motif that also contains the self-cleavage sites of both polarity strands.

In vitro and *in vivo* evidence indicates that specific cleavage of multimeric plus strand RNAs of PSTVd and related viroids requires: (1) rearrangement of the conserved central region, and (2) the action of one or more host-encoded nucleases. Other less efficient processing sites may also be used *in vivo*. Multimeric plus and minus strand RNAs of ASBVd and related viroids, in contrast, undergo spontaneous self-cleavage co-transcriptionally through hammerhead ribozymes to form linear monomers. Addition of certain chloroplast proteins acting as RNA chaperones facilitates this hammerhead ribozyme-mediated self-cleavage reaction. The final step in viroid replication, the ligation of linear monomers to form mature circular progeny, is catalyzed by DNA ligase 1 (redirected to accept RNA substrates) in the case of PSTVd, and by a plastid isoform of the tRNA ligase in members of the *Avsunviroidae* (Fig. 4).

Movement

Upon entering a potential host cell, viroids must move to either the nucleus (*Pospiviroidae*) or chloroplast (*Avsunviroidae*) before beginning replication. Available data suggest that PSTVd enters the nucleus as a ribonucleoprotein complex formed by the interaction of cellular proteins with specific viroid sequence or structural motifs. VirP1, a bromodomain-containing protein isolated from tomato, has a nuclear localization signal and binds to the terminal right domain of PSTVd. Proteins such as TFIIA and ribosomal protein L5 that bind to the loop E motif may also be involved in viroid transport into the nucleus. How ASBVd or other members of the family *Avsunviroidae* enter and exit the chloroplast is currently unknown.

To establish a systemic infection, viroids must leave the initially infected cell – moving first from cell-to-cell through plasmodesmata and then long distances through the host vasculature. Upon injection into symplastically isolated guard cells in a mature tomato leaf, fluorescently-labeled PSTVd RNA does not move. Injection into interconnected mesophyll cells, in contrast, is followed by rapid cell-to-cell movement through the plasmodesmata. Long distance movement of viroids, like that of nearly all plant viruses, occurs in the phloem where it follows the typical source-to-sink pattern of photoassimilate transport. Viroid movement in the phloem almost certainly requires formation of a ribonucleoprotein complex, possibly involving a dimeric lectin known as Phloem Protein 2 (PP2), the most abundant protein in phloem exudate. Movement of PSTVd in the phloem appears to be sustained by replication in supporting cells and is tightly regulated by developmental and cellular factors. For example, *in situ* hybridization reveals the presence of PSTVd in vascular tissues underlying the shoot apical meristem of infected tomato, but entry into the shoot apical meristem itself appears to be blocked. Other important control points for PSTVd trafficking are the bundle sheath-mesophyll boundary and that between palisade and spongy mesophyll in the leaf. By disrupting normal pattern of viroid movement it may be possible to create a plant that is resistant/immune to viroid infection.

Pathogenicity

Sequence comparisons of naturally-occurring PSTVd and CEVd variants, as well as infectivity studies with chimeric viroids constructed by exchanging the pathogenicity domains of mild and severe strains of CEVd, have clearly shown that the pathogenicity domain in the family *Pospiviroidae* contains important determinants of symptom expression. In addition, symptom expression is also affected by the rate of viroid accumulation, and sequence changes in the variable domain have been shown to regulate progeny titers in infected plants. Studies with Tomato apical stunt viroid (TASVd) revealed the presence of a third pathogenicity determinant in the left terminal loop. Also, a single U/A change position 257 in the central domain of PSTVd results in the appearance of severe stunting and a “flat top” phenotype in tomato, and a single base pair in the right terminal domain of TPMVd is a virulence determinant factor. In the family *Avsunviroidae*, determinants of pathogenicity have been mapped to either a tetraloop capping a hairpin stem in Chrysanthemum chlorotic mottle viroid (CChMVd) or an insertion that folds into a hairpin also capped by a tetraloop in PLMVd.

The ability of novel viroid chimeras to replicate and move normally from cell-to-cell implies certain basic similarities between their structures *in vitro* and *in vivo* but provides no information about the nature of the molecular interactions responsible for symptom development. Until recently, it was widely assumed that the mature viroid RNA was the direct pathogenic effector. Just like viruses, however, viroid replication is also accompanied by the appearance of a variety of small (21–24 nt) RNA molecules produced by the RNA silencing defensive response of their hosts. The role of these viroid-derived small RNAs (vd-sRNAs) in viroid pathogenicity is not yet clear, but the inverse relationship between accumulation levels of the mature viroid RNAs and the corresponding vd-sRNAs for members of the family *Avsunviroidae* suggests that the latter may regulate the titer of the former. In addition, vd-sRNAs containing the pathogenicity determinants of specific PLMVd variants that incite albinism or an intense yellow mosaic target and direct the cleavage (as predicted by RNA silencing) of host mRNAs coding for proteins involved in chloroplast biogenesis. The corresponding PLMVd-sRNAs have 5'-terminal Us, implicating Argonaute 1 in what likely are the initial alterations eliciting distinct chloroses. Also, recovery of tomato plants from the symptoms of severe PSTVd infections is preceded by the accumulation of vd-sRNAs (Fig. 5).

Viroid infections are accompanied by quantitative changes in a variety of host-encoded proteins. Certain of these are “pathogenesis-related” proteins whose synthesis or activation is part of a general host reaction to biotic or abiotic stress, but others appear to be more specific. In tobacco, PSTVd infection results in the preferential phosphorylation of a host-encoded 68 kDa protein that is immunologically related to an interferon-inducible, dsRNA-dependent mammalian protein kinase of similar size. The human kinase is differentially activated by PSTVd strains of varying pathogenicity *in vitro*, while infection of tomato by intermediate or severe strains of PSTVd induces the synthesis of PKV, a dual-specificity, serine/threonine protein kinase. Broad changes in host gene expression following infection by PSTVd and CEVd have been detected by complementary DNA macroarray and proteomic analyses, respectively.

Implications for Host Range

Possibly as a result of its involvement in the cleavage/ligation of progeny RNA, nucleotides in the central domain of PSTVd and related viroids appears to play an important role in determining host range. For example, a single nucleotide substitution in the

Fig. 5 A model for the role of RNA silencing in the pathogenicity and evolution of viroids and viral satellite RNAs. Replication of the subviral RNAs generates dsRNA intermediates that are processed by Dicer into 21- to 24-nt siRNAs (or vd-sRNAs), one strand of which are then incorporated into the RNA-induced silencing complex (RISC). If significant sequence identity exists between a region in the subviral RNA genome and a region in host gene mRNA (shown in red), RISC will target the host mRNA for cleavage leading to symptoms development. RISC can also target the subviral genome for degradation, forcing the subviral RNA to evolve and to adopt and maintain an RNA silencing-resistant secondary structure. From Wang, M.B., Bian, X.Y., Wu, L.M., *et al.*, 2004. On the role of RNA silencing in the pathogenicity and evolution of viroids and viral satellites. *Proceedings of the National Academy of Sciences of the United States of America* 101, 3275–3280, with permission, Copyright (2004) National Academy of Sciences, USA.

loop E motif results in a dramatic increase in the rate of PSTVd accumulation (and possibly replication) in tobacco. The biological properties of CLVd also suggest that this domain contains one or more host range determinants. CLVd appears to be a natural mosaic of sequences present in other viroids; phylogenetic analysis (Fig. 2) suggests that it can be considered to be a PSTVd-related viroid whose conserved central domain has been replaced by that of HSVd. Like HSVd (but not PSTVd or related viroids), CLVd can replicate and cause disease in cucumber.

Origin and Evolution

Much of the early speculation about viroid origin involved their possible origin as “escaped introns” (*i.e.*, descent from normal host RNAs). More recently, however, viroids have been proposed to represent “living fossils” of a precellular RNA world that assumed an intracellular mode of existence sometime after the evolution of cellular organisms. The presence of ribozymes in members of the *Avsunviroidae* strongly supports this view, although the recent characterization of circular long non-coding RNAs transcribed from DNA templates has rekindled the idea that viroids might have a host origin. No viroid is known to code for protein, a feature that is consistent with the possibility that viroids are phylogenetically older than introns.

The inherent stability of viroids and viroid-like satellite RNAs (structurally similar to viroids but functionally dependent on helper viruses) which arises from their small size and circularity would have enhanced the probability of their survival in primitive, error-prone RNA self-replicating systems and assured their complete replication without the need for initiation/termination signals. Some viroids (but not satellite RNAs or random sequences of the same base composition) also display structural periodicities with repeat units of 12, 60, or 80 nt. The high error rate of prebiotic replication systems may have favored the evolution of polyploid genomes, and the mechanism of viroid replication (*i.e.*, rolling-circle transcription of a circular template) provides an effective means of genome duplication.

Viroids and viroid-like satellite RNAs all possess efficient mechanisms for the precise cleavage of their oligomeric replication intermediates to form monomeric progeny. PSTVd and related viroids appear to require proteinaceous host factor(s) for cleavage, but others (members of the family *Avsunviroidae* and viroid-like satellite RNAs) contain ribozymes far smaller and simpler than those derived from introns. Thus, ASBVd and the other self-cleaving viroids may represent an evolutionary link between viroids and viroid-like satellite RNAs.

Phylogenetic evidence for an evolutionary link between viroids and other viroid-like subviral RNAs has been presented (Fig. 2). Among several subviral RNAs possibly related to viroids is carnation small viroid-like RNA, a 275 nt circular molecule with self-cleaving hammerhead structures in both its plus and minus strands that has a DNA counterpart. This retroviroid-like element shares certain features with both viroids and viroid-like satellite RNAs on the one hand, and with small RNA transcripts from newt and many other species on the other hand.

Glossary

Cross-protection A plant systemically infected by a mild virus strain will not develop additional symptoms when inoculated by a severe strain of the same virus. Most often, the severe strain does not multiply in the cross-protected plant.

Filiform symptom A leaf deformation symptom in which the limb is drastically reduced but not the veins, giving a shoe strings aspect to the leaf.

Transmission propensity A measure of vector importance quantifying the natural ability of a species to inoculate a plant with a virus under conditions that allow vectors to move and feed freely.

History and Taxonomy

Watermelon Mosaic Virus

Mosaic diseases of cucurbit crops were first reported in the 1920s and the early literature contains a diversity of names for viruses or virus diseases that were only partially characterized. In 1940, a severe watermelon (*Citrullus lanatus*) mosaic disease was reported in California, but the nomenclature of the causal agent remained controversial until 1979. In 1965, ten isolates from Southern USA of what was then called the watermelon mosaic virus (WMV) complex were compared. Based on cross-protection experiments, serological relationships and host range reactions they were divided into two groups: WMV1 and WMV2. WMV1 and WMV2 were considered as different viruses, also different from a watermelon mosaic isolate reported from South Africa in 1960. Further work in 1969 increased the confusion by concluding that WMV1 and WMV2 were strains of a same virus. In 1979, the situation was definitively clarified by demonstrating that WMV1 and WMV2 were indeed serologically distinct entities, and that WMV1 was closely related to *Papaya ringspot virus* (PRSV). Now, WMV1 is considered as the W strain of PRSV (PRSV-W), while WMV2 is referred to as *Watermelon mosaic virus* (WMV). In addition, the same authors showed that a watermelon mosaic virus isolate from Morocco was a third serological entity. This isolate is considered as a distinct virus species, *Moroccan watermelon mosaic virus* (MWMV), to which probably also belongs the South African isolate.

So, from the initial watermelon mosaic virus complex emerged three different virus species: *Watermelon mosaic virus*, *Papaya ringspot virus* and *Moroccan watermelon mosaic virus*.

Zucchini Yellow Mosaic Virus

An apparently new cucurbit virus was isolated in 1973 from a zucchini squash (*Cucurbita pepo*) plant in Northern Italy, this virus was described as a new potyvirus species, *Zucchini yellow mosaic virus* (ZYMV). In 1979, many melon (*Cucumis melo*) crops were devastated in Southwestern France by an apparently new virus disease, whose causal agent was tentatively named muskmelon yellow stunt virus. Very rapidly it appeared that it was a strain of ZYMV. Within a few years, ZYMV was reported in many countries on the five continents. In this regards, ZYMV appears as a typical example of an emerging plant virus.

Classification

Based on particle morphology, aphid transmissibility, serological relationships, ability to induce pinwheel cytoplasmic inclusions in host cells, genome organization and nucleotide sequences, WMV and ZYMV were identified as member species of the genus *Potyvirus*, family *Potyviridae*. Potyviruses belonging to several other species can infect cucurbit crops including PRSV-W and related viruses: MWMV, *Zucchini yellow fleck virus* (ZYFV), *Zucchini tigre mosaic virus* (ZTMV), *Zucchini shoestring virus* (ZSTV), *Algerian watermelon mosaic virus* (AWMV), *Sudan watermelon mosaic virus* (SuWMV), *Wild melon vein banding virus* (WMVBV), *Melon vein banding mosaic virus* (MVBV), *Telfairia mosaic virus* (TeMV), *Cucurbita vein-banding virus* (CVBV), *Turnip mosaic virus* (TuMV), *Clover yellow vein virus* (CIYVV) and *Bean yellow mosaic virus* (BYMV). Except for PRSV-W, MWMV and ZTMV, these viruses have either only limited geographic distribution or minor economical incidence in cucurbit crops.

Molecular analyses based on the coat protein (CP) coding sequence revealed that cucurbit-infecting potyviruses belong to several “clusters” of closely related species: ZYMV, WMV and MVBV belong to a cluster that contains mostly legume-infecting potyviruses, whereas PRSV, MWMV and 6 other viruses are grouped in a “PRSV-like” cluster containing mostly cucurbit-restricted viruses (Fig. 1).

Fig. 1 Taxonomy, based on coat protein amino-acid sequences, of potyviruses including cucurbit-infecting ones (in bold). Branch lengths indicate the molecular divergence of viruses (the scale bar represents 0.05 mutations per residue). Figures at some nodes represent bootstrap values (in %), indicating the robustness of each node. Only values above 75% are indicated.

Symptomatology

Watermelon Mosaic Virus

WMV induces a diversity of symptoms depending on the isolate and the host cultivar. On leaves, symptoms are mosaics, vein banding, more or less severe leaf deformations and filiform symptom. On fruits, some isolates induce discoloration and greening on yellow fruit zucchini squash cultivars, while they will not affect fruit yield and quality in green fruit cultivars. Mosaic and discoloration are also observed on leaves and fruits of some melon cultivars (Fig. 2).

Zucchini Yellow Mosaic Virus

Since its first detection, ZYMV was recognized as a virus causing extremely severe symptoms leading to complete yield losses in the case of early contamination. This severe symptomatology was probably an important factor for the rapid identification of ZYMV soon after its first outbreaks in many countries. In melon, leaf symptoms include vein clearing, yellow mosaic, leaf deformation occasionally with blisters and enations, often with severe plant stunting. Some ZYMV isolates induce a rapid and complete wilt in

Fig. 2 Mosaic symptoms on a leaf and fruit of a melon plant infected by a moderately severe WMV isolate.

Fig. 3 Severe mosaic and deformations on leaves and fruits of a zucchini squash plant infected by ZYMV.

cultivars possessing the *Fn* gene. On fruits, a diversity of symptoms is observed: external mosaic or necrotic cracks, internal marbling and hardening of the flesh. Seeds are occasionally severely deformed and have poor germination rates. In zucchini squash, symptoms are very severe on leaves with mosaic, yellowing, leaf distortion and sometimes very severe filiform symptom. Fruits are generally severely misshaped with prominent knobs and are of course unmarketable (**Fig. 3**). In cucumber (*Cucumis sativus*) and watermelon, mosaic and deformations are generally observed on leaves and fruits.

Synergism and Antagonism

Synergism has been observed between WMV or ZYMV and other cucurbit-infecting viruses. This synergism can be expressed either by increase in virus multiplication rates or by more severe symptoms. Significant increase in Cucumber mosaic virus (CMV) multiplication rate was observed in cucumber plants co-infected by ZYMV. CMV could also partially overcome a resistance in cucumber when in mixed infection with ZYMV. In grafted cucumbers, double infection by CMV and ZYMV induces a severe and rapid wilting reaction, not observed in single infection by CMV or ZYMV. ZYMV was shown to facilitate the entry of CMV in cucumber xylem in co-infection. When WMV or ZYMV are in mixed infection with the polerovirus Cucurbit aphid-borne yellows virus (CABYV), CABYV multiplication rate and symptom intensity are increased. As for other potyviruses, these synergetic effects could be related to the strong silencing suppressor activity of WMV and ZYMV HC-Pro.

In mixed infections of ZYMV and WMV, the multiplication rate of ZYMV is not affected whereas WMV accumulation is significantly reduced, but the virus is still readily transmitted by aphids. In field conditions, early epidemics of ZYMV seem to hinder WMV spread.

Infection of ZYMV limits establishment and severity of powdery mildew infection in wild squash populations, as well as the incidence of bacterial wilt caused by *Erwinia tracheiphila*. The lower bacterial infection appears related to a reduction of floral volatile emissions in ZYMV-infected plants, resulting in a lower attractiveness for the cucumber beetles that transmit the bacteria.

Geographic Distribution

Both WMV and ZYMV are now widely distributed in the major cucurbit production areas worldwide. Their geographic distributions are broadly overlapping and frequent mixed infections are observed in the fields.

For unknown reasons, WMV appear to be rare or absent in cucurbits in subtropical or tropical areas. For instance, in exhaustive surveys conducted in Nepal, Sudan and French Western Indies no WMV was detected, although ZYMV was relatively abundant. In Florida, WMV is frequent in Northern and Central counties but is not detected in Southern counties while ZYMV can be found throughout the state. This cannot be related to a lack of potential WMV vectors or reservoirs because both are abundant in tropical or subtropical areas.

ZYMV is present worldwide in almost all countries where cucurbits are grown, under temperate, Mediterranean, subtropical and tropical climatic conditions. It affects highly mechanized cropping systems – such a glasshouse crop production in Northern Europe – as well as more traditional agroecosystems – such as flood irrigated crops on the Nile banks. ZYMV has been reported in very remote areas including semi-desertic regions or islands.

Host Range

WMV has a relatively wide experimental host range for a potyvirus. It infects over 170 species in 26 mono- or dicotyledonous families. Besides cucurbits, WMV causes mosaic diseases in legumes (pea, bean) and orchids (vanilla, *Habenaria radiata*). It has been described on many cultivated and ornamental hosts, including *Panax ginseng* and *Lagerstroemia indica*. It also infects many weeds, either annual or perennial, that can serve as alternative hosts. Generally, naturally infected weeds do not present evident symptoms of viral infection.

ZYMV has a relatively narrow host range. In natural conditions, it infects mostly cultivated or wild cucurbits but also a few flower species (*Consolida ajacis*, *Althea rosea*, *Begonia sempervirens*) or weeds.

Diagnostic Methods

The confusion that was prevalent in the early descriptions of watermelon mosaic diseases was mainly due to the convergence of symptoms caused by WMV, PRSV and MWMV in cucurbits and to the lack of proper diagnostic tools. Symptomatology and virus particle morphology were clearly insufficient to differentiate these viruses. The production of specific polyclonal antisera, and the development of simple serological tests, such as the gel double-diffusion test in agar containing sodium dodecyl sulphate and sodium azide (SDS-ID), brought a major contribution to the proper diagnosis of cucurbit potyviruses. In particular, this method contributed to the rapid and unequivocal identification of ZYMV in several countries soon after its first observation. Now, DAS-ELISA is generalized and commercial kits are available for WMV and ZYMV. Commercial dip-stick serological tests based on the lateral flow technique have also been developed that allow an easy and rapid diagnosis of ZYMV in the fields.

Monoclonal antibodies (MAbs) have been produced for ZYMV and WMV. They proved to be very useful to study the serological variability and to differentiate ZYMV and WMV subgroups. They have also been used successfully to analyze virus interactions, and in particular cross protection efficiency and specificity. Nanobodies, i.e., camel-derived variable domains of the heavy chain antibodies, have also been obtained against ZYMV CP.

Many nucleotide sequences are now available for ZYMV and WMV, particularly in the coat protein (CP) coding region, what allowed the development of specific primers for each virus. Loop-mediated isothermal amplification (LAMP) has also been developed for the diagnostic of WMV and ZYMV.

Vector Relationships

WMV is transmitted by at least 35 aphid species in 19 genera. Fewer aphid species were tested for their ability to transmit ZYMV, and 11 were identified as ZYMV vectors. *Aphis craccivora*, *Aphis gossypii*, *Macrosiphum euphorbiae* and *Myzus persicae* are efficient WMV and ZYMV vectors. Some aphid species were shown to be poor or non-vectors of WMV and ZYMV what suggests some level of specificity in the virus-vector interaction.

WMV and ZYMV are transmitted on the non-persistent mode: they are acquired and transmitted during very short probes (a few seconds to minutes), and their retention period in the vector is relatively short (a few hours).

WMV and ZYMV as typical potyviruses require the presence of a virus-encoded helper component (HC-Pro) protein for transmission. HC-Pro from WMV and ZYMV are interchangeable and both mediate efficiently the transmission of purified virions of both species.

Several ZYMV isolates that have lost aphid transmissibility have been characterized, and a unique feature for this virus is that single amino acid mutants have been identified in the three domains important for transmission. ZYMV-NAT has a A to T substitution in the DAG motif in the CP, ZYMV-PAT a T to A substitution in the PTK motif and ZYMV-R1A a K to E substitution in

the KLSC motif, both in the HC-Pro. These mutants led to the identification of an interaction between the HC-Pro and CP through their PTK and DAG domains.

The non-transmissible isolate ZYMV-NAT (having the DTG motif in the CP) could be transmitted by aphids from plants infected concomitantly by a transmissible isolate of PRSV. This occurred through hetero-encapsidation, a phenomenon by which ZYMV RNA is completely or partially encapsidated by the functional PRSV CP. An aphid non-transmissible isolate deficient for the HC-Pro can also be transmitted by aphids when in mixed infection with an isolate that has a functional HC-Pro. The transmissible isolate provides its functional HC-Pro to mediate the transmission of the deficient isolate. These two mechanisms can contribute to the maintenance, in natural conditions, of variants which have lost their vector transmissibility.

An interesting interaction has been observed between ZYMV and *A. gossypii*, an aphid vector colonizing cucurbit crops. *A. gossypii* lives longer and produce more offspring on ZYMV infected than on non-infected plants. In addition, more alatae are produced on infected plants, which may stimulate ZYMV spread. These phenomena might be related to the observed changes in phloem exudates composition (free amino acids, sugars) in virus infected plants.

Epidemiology

Virus Sources

WMV has not been described as seed borne in cucurbits or other crops, but may be transmitted through vegetative propagation in vanilla. ZYMV seed transmission has long remained controversial, with estimated rates ranging from 0% to 18%. Seed transmission was observed in naked seed pumpkin. Using RT-PCR detection, a vertical transmission rate of 1.6% was observed in *C. pepo* subsp. *texana*. The vertically-infected plants were symptomless and had low virus titers, but they could constitute sources for further horizontal transmission, either mechanically or by aphids. Pollen transmission occurred at a rate of only 0.13%, indicating that most seed transmission is *via* the ovule.

Another possible way for long distance dissemination of ZYMV is through the globalization of vegetable production and trade. It has been shown that ZYMV infected fruits imported from Central America into Europe could be very efficient virus sources for aphids.

Virus sources from which epidemics will initiate could be infected overwintering weeds or crops. In tropical and sub-tropical regions, cucurbit crops or weeds are growing all year round, and viruses could easily move from an old infected crop or cucurbit weed to a young planting. In more temperate regions non-cucurbit weeds were found to be efficient reservoirs for WMV but not for ZYMV. However, a few ornamental plants such as *Begonia sempervirens* were shown to be involved in ZYMV overwintering in Southern France. Winter protected crops could contribute to ZYMV overwintering in Mediterranean regions and residential gardens were found important sources of ZYMV in California.

Efficient Vectors

Many potential aphid vector species have been identified for WMV and ZYMV. A study was conducted to compare the vector capacity of two aphid species, one colonizing cucurbits (*A. gossypii*), the other not (*A. craccivora*). Two parameters were used. Transmission efficiency was measured in the laboratory with single aphids exposed in sequence to an infected plant and then to four healthy plants. Transmission propensity was measured by arena tests (more representative of natural conditions) in which aphids could move between plants and feed without interference. It was shown that *A. craccivora* had both a higher efficiency and propensity to disseminate ZYMV than *A. gossypii*. This highlights the importance of non-colonizing transient vector species in the epidemiology of ZYMV. In addition to vector transmission, ZYMV transmission has been shown to occur in zucchini squash either through direct contact or trampling on leaves of neighboring plants or through tools used for collecting fruit.

Pattern of Spread

The same general pattern is observed for WMV and ZYMV. The first contaminations occur generally shortly after planting, depending upon the availability of virus sources in the environment. Then, aphid flights, particularly of non-colonizing species, spread the virus from the primary infection foci to the rest of the crop, what corresponds to the secondary virus spread. The diseased plants are often distributed in large patches that rapidly extend and join each others, leading to the complete contamination of the crop within a few weeks. Simultaneously, the infected crop will serve as a source of virus to contaminate weeds or nearby young plantings. Epidemic development curves have an overall S shape, fitting generally well to the logistic model.

Control Methods

Prophylactic Measures

Prophylactic measures are intended to prevent or limit the contact of viruliferous aphids with cultivated plants. They are not specific for a particular virus and are generally efficient for all aphid-borne viruses. These include careful weeding near plantings

and avoiding overlapping crops in the same area to reduce virus and aphid sources near new plantings. When possible, manipulation of planting dates can avoid exposing young plants to peaks of vector populations. Plastic mulches have a repelling action on aphids and significantly delay WMV and ZYMV spread. However, they confer only a temporary protection that is limited to the early stages of the crop, because their efficiency decreases when plant growth covers their surface. Row covers of different types (unwoven, perforated plastics...) can also be used; they physically prevent winged aphids from reaching the plants, but they must be removed to allow insect pollination necessary for cucurbits. Both methods have a major drawback: they require a lot of plastic material that farmers must dispose in an ecologically sound way after the crop cycle. Tall non-host barriers (millet, *Pennisetum glaucum*) planted upwind of potential infection sources also contribute to reducing virus infection. Insecticides applications have been generally found inefficient in limiting WMV and ZYMV spread. This is to relate to the large number of winged aphids that land on the plants and to the rapidity of the transmission process. Oil applications can delay virus spread when inoculum pressure is moderate. When applicable, a one-month crop-free period has been shown to be efficient in limiting ZYMV spread. On-farm hygiene practices such as decontamination of tools are also recommended to limit virus spread through contact transmission.

Cross-Protection

Cross-protection has been developed at a commercial level to protect cucurbit crops against ZYMV. The principle is simple: when a mild virus isolate (i.e., that has no significant impact on commercial yield) is inoculated to young seedlings, it protects the plant from subsequent contaminations by severe isolates of the same virus. The mechanism appears related to virus-induced gene silencing. The mild strain ZYMV-WK is a natural variant of a severe aphid non-transmissible isolate. Although efficient against most ZYMV isolates (Fig. 4), ZYMV-WK does not protect against very divergent isolates such as those from Réunion Island indicating some specificity in the protection. A single amino acid change (R to I) in the FRNK conserved domain of the HC-Pro is responsible for symptom attenuation of ZYMV-WK. A complete technological package (mild strain production, quality control protocols, and inoculation machines) has been developed to implement commercially ZYMV cross-protection. Mild WMV isolates have been reported that could also have a potential for cross-protection but they have not been used commercially.

Resistant Cultivars

The use of virus-resistant cultivars is probably the easiest and cheapest way to control plant viral diseases at the farmer's level. Breeding for resistance still mainly relies upon search for resistance characters in germplasm collections and introgression of the resistance gene(s) into commercially acceptable cultivars. Considerable efforts have been made to look for resistance to WMV and ZYMV in genetic resources and some WMV- or ZYMV-resistant commercial cultivars are now available. Some resistance genes confer complete and durable resistance (such as the recessive *zym* gene in cucumber) while others confer only partial resistances or may be overcome by virus evolution (such as the dominant *Zym* gene in melon). An interesting situation is observed for ZYMV resistance in squash. Although the resistance level was high in the original accession of *Cucurbita moschata* in which the resistance was identified, when transferred through interspecific crosses to zucchini squash (*C. pepo*), the resistance phenotype was different: ZYMV multiplies but the plants present only very mild symptoms (this is called tolerance). However, tolerance appears not to be stable since aggressive variants of the virus (i.e., causing severe symptoms in tolerant plants) may emerge in these plants. A single amino acid change in the P3 gene is sufficient to confer this aggressive phenotype. However, the aggressive variants are counter-selected when in competition with common ZYMV isolates in susceptible cucurbits. This genetic load associated with aggressiveness could be a factor that will make the tolerance durable. In melon, a resistance to WMV and ZYMV transmission by

Fig. 4 Cross-protected zucchini crop in greenhouse conditions. Left: unprotected plants infected with a severe strain of ZYMV; right: plants preventively inoculated with the mild strain ZYMV-WK, protected against infection with severe strains.

A. gossypii was found to be governed by the single dominant gene *Vat*. This gene is present in many commercial cultivars, but confers only limited protection in the fields, probably because WMV and ZYMV are also transmitted by many other aphid species in natural conditions.

In the last three decades, attempts were made to obtain WMV and ZYMV transgenic resistant plants using the pathogen derived resistance approach. Different constructs were tested to obtain resistant WMV or ZYMV plants: untranslatable or full-length CP gene, ribozymes. Freedom II, a transgenic squash hybrid containing the WMV and ZYMV CP genes was released in the USA in 1995, as the first virus-resistant transgenic crop to be commercially cultivated in the world. It proved to have a very efficient resistance to WMV and ZYMV in field conditions. Similar hybrids are presently grown mainly in South Eastern USA, particularly during late summer and fall when WMV and ZYMV inoculum pressure are high. Surprisingly, protection against ZYMV infection in transgenic squash presented indirect costs: higher predation by beetles and higher incidence of bacterial wilt.

Exogenously applied dsRNA molecules deriving from the ZYMV genome conferred variable levels of resistance to ZYMV in experimental conditions: protection up to 82% was achieved in cucumber using a 588 bp fragment of the HC-pro. Inoculation of cucumber with an apple latent spherical virus vector harboring part of ZYMV genome prevented subsequent experimental infection by ZYMV, and also had a curative effect on ZYMV-infected plants. Recently, melons and cucumbers either silenced or mutated in the eukaryotic translation initiation factor 4E (eIF4E) that is required for potyvirus infection, were found to be resistant to several viruses including ZYMV.

Variability

Only limited biological variability has been reported for WMV. This concerns mainly differences in symptom intensity, host range or aphid transmissibility. Among the few host range specificities, the ability or not to infect systemically *Chenopodium quinoa* is related to a point mutation in WMV CP.

In contrast, from its first description, ZYMV appeared to have a very important biological diversity in host range and symptomatology on susceptible hosts, with isolates producing mild or atypical mosaic symptoms, necrosis or wilting reactions. Different pathotypes could be differentiated on melon or squash varieties possessing resistance genes. Important variability has also been observed in aphid transmissibility and several aphid non- or poorly-transmissible isolates have been described.

Limited serological variability was observed in WMV and ZYMV when polyclonal antibodies were used. However, the development of monoclonal antibodies against WMV and ZYMV allowed the characterization of serotypes closely correlated to the molecular variability.

The molecular variability of ZYMV and WMV was assessed first on the CP region, particularly the N-terminal part of the CP that is known for potyviruses to be highly variable and is frequently used for molecular studies. Besides, more than 50 complete sequences are now available for both ZYMV and WMV. For ZYMV, 3 major molecular groups were defined. Groups B and C contain isolates from specific geographic origins (Reunion Island, Singapore, Vietnam, Australia and East Timor for group B; China, Vietnam and Poland for group C) whereas group A contains worldwide isolates, including the first ZYMV isolates described in the 1970s in Europe. Within group A, 6–7 subgroups were defined without strong geographic structure (Fig. 5). Molecular analyses have allowed, in a few cases, tracking the putative origins of ZYMV strains emerging in a new area.

For WMV, the first studies indicated the presence of 3 major molecular groups more or less correlated with the geographic origin of the isolates: Group 1 in Europe, the Mediterranean Basin and part of Asia, Group 2 in South America and the Pacific area and Group 3 in Eastern Asia. With the increase of the number of sequences available, the situation has become more complex (Fig. 5), and evidence for long-distance exchanges of genetic diversity was observed, sometimes followed by strain replacement as observed in several European countries in the 2000s.

Genetics and Evolution

WMV and ZYMV genome organization is very similar to that of other potyviruses sequenced so far. The single-stranded, positive-sense RNA genome (9.6 kb for ZYMV, 10 kb for WMV excluding the polyadenylated 3' extremity) is translated as a single polyprotein that is self-cleaved in 10 functional proteins, with an 11th protein expressed through replication slippage in the P3 coding region.

The full-length sequence revealed that WMV is very closely related to the legume-infecting soybean mosaic virus (SMV); however, the P1 protein is 135 amino-acids longer than that of SMV, and the N-terminal half of the P1 shows no relation to SMV but is 85% identical to another legume-infecting potyvirus, bean common mosaic virus (BCMV). This suggests that WMV has emerged through an ancestral recombination event between a SMV-like and a BCMV-like potyvirus. SMV and BCMV have a narrow host range, mostly restricted to legumes, while WMV is one of the potyviruses with the broadest host range, including monocots and dicots. The impact of its recombinant nature on WMV biological properties remains unknown. Some SMV isolates from China have the same recombination with BCMV in the 5' part of the genome as WMV but they did not infect watermelon even though, contrary to regular SMV isolates, they could infect common bean.

Partial and complete sequence data indicate the frequent presence of intraspecific recombinants in WMV. By sequencing the full-length genome of putative recombinants, recombination points were characterized in different parts of the genome, with a

Fig. 5 Distance tree based on the nucleotide sequence of the coat protein coding region of ZYMV (left) and WMV (right), and showing the main molecular groups currently acknowledged for these viruses. Branch lengths indicate the molecular divergence between sequences (the scale bar represents 0.02 and 0.005 mutations per site for ZYMV and WMV respectively). Figures at some nodes represent bootstrap values (in %), indicating the robustness of each node.

hotspot in the P3-CI region. In France, recombinants between Groups 1 and 3 were observed in the few years following the introduction of Group 3, but they did not become prevalent in populations.

In the case of ZYMV, sequence analysis software suggest that recombination might have taken place, but the situation is not as clear cut as for WMV.

Besides recombination, viral genomes also evolve by mutations that take place during replication. In the case of ZYMV, the biological consequences of several point mutations that emerged in natural conditions were assessed by molecular studies: sequences of closely related strains with different biological properties were compared, and the mutations observed – particularly non-silent mutations located in conserved domains – were introduced by site-directed mutagenesis in an infectious cDNA of ZYMV in order to check if the mutation alone is sufficient to induce the difference in biological properties.

Molecular studies have thus shown that single point mutations in HC-Pro or P3 protein of ZYMV were important for symptomatology. Similarly, single mutations in HC-Pro or CP greatly affect aphid transmissibility. For unknown reasons, some ZYMV isolates such as ZYMV-E15 seems to be particularly prone to mutations and many variants (mild, aphid non-transmissible, aggressive or virulent) have been derived from this isolate.

Biotechnological Application

The development of infectious cDNA clones of ZYMV brought the possibility of using ZYMV as a biotechnological tool to produce proteins of pharmaceutical or crop protection interest. The gene coding for the protein of interest can be inserted in the ZYMV genome either between the P1 and HC-Pro genes or between the NIb and CP genes. For optimal protein production, it is possible to use clones that have the mutation in the FRNK domain so that they produce mild symptoms and do not affect plant growth. The protein may be produced in the edible cucurbit fruits that could be used directly for oral administration. Several molecules of pharmaceutical interest have been efficiently produced through this technology: the human interferon-alpha 2, antiviral and antitumor proteins MAP30 and GAP31 and a mite allergen. This technology also provided a way to produce large amounts of nucleocapsid proteins of 5 tospoviruses that could be used for immunization and production of specific antibodies. Finally, the *bar* gene coding for a phosphinothricin acetyltransferase that confer resistance to glufosinate ammonium based herbicides has been inserted into the mild ZYMV expression vector. In weed infested plots, this construct efficiently protected inoculated zucchini squash plants from damage caused by an herbicide treatment that completely destroyed the weeds. In addition, these plants were protected against severe ZYMV isolates. It is interesting to see that ZYMV, which emerged as the most damaging cucurbit virus in the last decades, can be manipulated and used for the benefit of human health and agriculture.

EDITORS IN CHIEF

Dennis H. Bamford, PhD, is Professor Emeritus of Virology at the Faculty of Biological and Environmental Sciences, University of Helsinki, Finland. He obtained his PhD in 1980 from the Department of Genetics, University of Helsinki. During 1981–1982 he was an EMBO postdoctoral fellow at the Public Health Research Institute of the City of New York, United States, and during 1983–1992 he worked as a Senior Scientist at the Academy of Finland. In 1993 he was appointed Professor of General Microbiology at the University of Helsinki. He was awarded the esteemed Academy Professorship twice, in 2002–2007 and 2012–2016, and he also served twice as the Director of the Finnish Center of Excellence (in Structural Virology, 2000–2005, and in Virus Research, 2006–2011). Prof. Bamford has had continuous external research funding (e.g., from several European Union, Academy of Finland, TEKES and Jusélius Foundation funds, as well as the Human Frontier Science Program). He is an EMBO member and has held several positions of trust in scientific and administrative organizations.

Prof. Bamford has published approx. 400 articles in international peer-reviewed journals in virology, microbiology, biochemistry, and molecular biology (36 of them in high impact journals). About half of the primary articles have been published with international collaborators showing high international integration. He has also been invited to give 56 keynote and plenary presentations in major international meetings. Prof. Bamford has supervised over 35 Master's and

over 40 PhD theses. Seven of his graduate students or post docs have obtained a professorship and a similar number have a principal investigator status. Prof. Bamford has studied virus evolution from a structure-centered perspective, showing that seemingly unrelated viruses, such as bacteriophage PRD1 and human adenovirus have similar virion architecture. When the corona virion architecture was gradually revealed, it was observed that its structural elements were close to those seen in RNA bacteriophage phi6 so that phi6 has been actively used as surrogate for pathogenic viruses - quite a surprise!

Dr. Mark Zuckerman is Head of Virology, Consultant Medical Virologist, and Honorary Senior Lecturer at South London Specialist Virology Centre, King's College Hospital NHS Foundation Trust and King's College London Medical School, Department of Infectious Diseases, School of Immunology and Microbial Sciences in London, United Kingdom. His interests include the clinical interface between developing molecular diagnostic tests relevant to the local population of patients, respiratory virus infections, herpesvirus infections in immunocompromised patients and blood-borne virus transmission incidents in the healthcare setting. He has chaired the UK Clinical Virology Network, Royal College of Pathologists Virology Specialty Advisory Committee and Virology Examiners Panel and is a member of the Specialty Advisory Committee on Transfusion Transmitted Viruses. He is a co-author on four editions of the "Mims' Medical Microbiology" textbook, has written chapters in a number of other textbooks and has over 100 publications in international peer-reviewed journals and is an associate editor for two journals.

SECTION EDITORS

Claude Fauquet received his PhD in biochemistry from University Louis Pasteur in Strasbourg, France in 1974. Dr. Fauquet joined the Institut de Recherche pour le Développement (IRD) and worked there as a plant virologist for 28 years, and served in Ivory Coast, West Africa for 14 years. In 1991, he founded the International Laboratory for Tropical Agricultural Biotechnology (ILTAB) at The Scripps Research Institute, CA, United States. ILTAB was then hosted by the Donald Danforth Plant Science Center, St. Louis, MO, from 1999 to 2012. In 2003, he co-founded the Global Cassava Partnership for the 21st Century (GCP21), which he directed until 2019 and which goal is to improve the cassava crop worldwide.

Dr. Fauquet is an international leader in plant virology including taxonomy, epidemiology, molecular virology, and in gene-silencing as an antiviral strategy. He was Secretary of the International Committee on Taxonomy of Viruses (ICTV) for 18 years and the editor of several ICTV Reports including the VIIIth ICTV Report in 2005.

He has published more than 300 research papers in reviewed journals and books. He is a fellow of the American Association for the Advancement of Science, of the American Phytopathological Society and a member of the St. Louis Academy of Sciences. In 2007, Dr. Fauquet was knighted “Chevalier de l’Ordre des Palmes Académiques” by the French Minister of High Education and Research.

Dr. Michael Feiss is Professor Emeritus in the Department of Microbiology and Immunology of the Carver College of Medicine at the University of Iowa, IA, United States. Dr. Feiss received his PhD in Genetics at the University of Washington followed by a postdoctoral traineeship in the laboratory of Dr. Allan Campbell at Stanford. Dr. Feiss is a microbial geneticist who studies virus assembly with an emphasis on how a DNA virus, bacteriophage lambda, packages viral DNA into the empty prohead shell. The lab investigates how sites in the viral DNA orchestrate the initiation and termination of the DNA packaging process. This work includes comprehensive examination of the DNA recognition sites. A related interest is study of terminase, the viral DNA packaging enzyme, including the functional domains for protein–DNA and protein–protein interactions. A second focus has been the roles of the bacterial host’s IHF and DnaJ proteins in the lytic life cycle of the virus. More recent work has involved a genetic dissection of the role of terminase’s ATPase center that powers translocation of viral DNA into the prohead. This interest in the ATP hydrolysis-driven packaging motor involves a multidisciplinary collaboration examining the kinetics of DNA packaging during individual packaging events. Finally, recent studies have also looked at how the packaging process has diverged among several lambda-like phages, including phages 21, N15, and Gifsy-1.

Elizabeth E. Fry is a senior postdoctoral scientist in structural biology at the University of Oxford, Oxford, United Kingdom, where she received her DPhil. for studies relating to the structure determination of Foot-and-Mouth Disease Virus. Specializing in structural virology, Dr. Fry has studied many virus/viral protein structures but her primary focus is on picornavirus structure and function, in particular receptor interactions and virus uncoating. She is particularly interested in rationally designing virus-like-particles as next generation vaccines to reduce the inherent risks in handling live viruses.

Said A. Ghabrial[†] received his BSc in 1959 from Cairo University, Cairo, Egypt, and his PhD from Louisiana State University, Baton Rouge, LA, United States, in 1965. Dr. Ghabrial did postdoctoral research at the University of California, Davis, CA, United States, before returning to Cairo, where he served as a plant virologist in the Ministry of Agriculture. He returned to the United States in 1970 to do postdoctoral research at Purdue University, West Lafayette, IN. In 1972, he joined the Plant Pathology Department at the University of Kentucky, Lexington, KY, United States, where he rose to the rank of professor in 1986 and worked until 2013.

Dr. Ghabrial has served as an associate and senior editor of *Phytopathology*. He served on the editorial boards of the *Encyclopedia of Virology*, 3rd edition and *Encyclopedia of Plant Pathology*, and edited a thematic issue of *Advances in Virus Research* on "Mycoviruses". He was a member of the American Phytopathological Society (APS) and the American Society for Virology (ASV); in July 2002 he was elected as a Fellow of the American Phytopathological Society. He also acted as Chair of the ICTV Subcommittee on Fungal Viruses in 1987–1993 and 2011–2014.

His long professional career allowed him to make many scientific achievements in phytopathology and virology. Among them are molecular dissection of a legume-infecting RNA virus, bean pod mottle virus (BPMV), development of BPMV-based vectors, discovery of a transmissible debilitation disease of the phytopathogenic ascomycete, *Helminthosporium victoriae* (*Cochliobolus victoriae*), establishment of a viral etiology of the *H. victoriae* disease, and advancement of structural biology of diverse fungal viruses.

Eric Hunter, PhD, is Professor of Pathology and Laboratory Medicine at Emory University, Atlanta, GA, United States. He serves as Co-Director of the Emory Center for AIDS Research and is a Georgia Research Alliance Eminent Scholar.

Dr. Hunter's research focus has been the molecular virology and pathogenesis of retroviruses, including human immunodeficiency virus. He has made significant contributions to the understanding of the role of retroviral glycoprotein structural features during viral entry and providing unique insights into the assembly and replication of this virus family. In recent years the emphasis of his research has been on HIV transmission and pathogenesis, defining the extreme genetic bottleneck and selection of viruses with unique traits during HIV heterosexual transmission. He has described the selection of fitter viruses at the target mucosa, a gender difference in the extent of selection bias, and a role for genital inflammation in reducing selection. His research has defined the impact of HIV adaptation to the cellular immune response on immune recognition and control of HIV after

transmission, as well as on virus replicative fitness in vitro and in vivo. Recent work highlights the roles that virus replicative fitness and sex of the host play in defining disease progression in a newly infected individual. His bibliography includes over 300 peer-reviewed articles, reviews, and book chapters. He has also been the recipient of four NIH merit awards for his work on retrovirus and HIV molecular biology.

Dr. Hunter served as the Editor in Chief of the journal *AIDS Research and Human Retroviruses* for 10 years. He was Chair of the AIDS Vaccine Research Subcommittee which is charged with providing advice and consultation on AIDS vaccine research to the National Institute of Allergy and Infectious Diseases and continues to serve on editorial boards for several academic journals and on external advisory committees for several government, academic, and commercial institutions.

Ilkka Julkunen graduated as an MD/PhD in 1984 from the Department of Virology, University of Helsinki, Helsinki, Finland. He worked as a postdoctoral research fellow at Memorial Sloan-Kettering Cancer Center in New York, United States, in 1986–1989, followed by positions as a senior scientist, group leader and research professor at Finnish Institute for Health and Welfare in 1989–2013. In 2013 he became a Professor of Virology at the University of Turku, Turku, Finland. The research interests of Dr. Julkunen have concentrated on innate and adaptive humoral immunity in viral and microbial infections. He has studied intracellular signaling and RIG-I and TLR-mediated activation of interferon system in human macrophages and dendritic cells and stable cell lines in response to human and avian influenza, Sendai, Zika and coronavirus infections. In addition, he has analyzed the downregulation of innate immunity by viral regulatory proteins from influenza, HCV, flavi-, filo- and coronaviruses. He has expertise in vaccinology, biotechnology and development of methods to analyze antiviral immunity, he has also been actively involved in research training and collaborations with biotechnological industry.

[†]Deceased.

Peter Krell started his career in virology early as a summer high school student working for the Canadian Forestry Service studying the resistance of nuclear polyhedrosis viruses (now called baculoviruses) to environmental exposure with Dr. Fred T. Bird at the Insect Pathology Research Institute in Sault Ste. Marie, ON, Canada. He received his BSc and MSc in biology from Carleton University studying the iridovirus *Tipula Iridescent Virus* with Dr Peter Lee, in Ottawa, the Canadian capital. For his PhD he headed east to Dalhousie University in Halifax, Nova Scotia on the Atlantic coast. In addition to enjoying the salt sea air, fresh cod, lobster and mussels, he studied the molecular biology of polydnaviruses under the guidance of Dr Don Stoltz. Heading south to Texas A&M University in College Station, TX, United States, as a Postdoctoral Fellow he worked with Dr. Max Summer, of baculovirus fame, and Dr. Brad Vinson continuing to study polydnaviruses, but also became steeped in the early days of molecular baculovirology. He then accepted a faculty position in the Department of Microbiology and Immunology at the University of Guelph in Guelph, ON, Canada. There he switched to baculovirus research, which was more tractable, due in part to available cell cultures and focused on viral DNA replication and functional genomics,

particularly on chitinase, cathepsin and ME53. In collaboration with Dr. Eva Nagy he studied molecular biology of different animal viruses, notably Fowl Avian adenoviruses and their development as vaccine vectors, but also on the birnavirus infectious pancreatic necrosis virus, the coronavirus porcine endemic diarrhea virus, fowlpox virus and the paramyxovirus Newcastle disease virus. He has been involved extensively with virus taxonomy, being active in the International Committee on Taxonomy of Viruses (ICTV) as member of the *Polydnaviridae* and *Baculoviridae* study groups, national representative of Canada on the ICTV, member of the Executive Committee for the ICTV and Chair of the ICTV Invertebrate Virus Subcommittee. In terms of governance, Peter Krell was President of the Canadian Society of Microbiology, Secretary and later President of the Society for Invertebrate Pathology, as well as being on the Editorial Boards of the *Canadian Journal of Microbiology* and the *ASM Journal of Virology*. While at the University of Guelph, he rose through the ranks to Professor and is currently University Professor Emeritus.

Mart Krupovic is the Head of the Archaeal Virology Unit in the Department of Microbiology at the Institut Pasteur of Paris, France. He received his MSc in Biochemistry in 2005 from the Vilnius University, Vilnius, Lithuania and PhD in 2010 in general microbiology from the University of Helsinki, Helsinki, Finland. His current research focuses on the diversity, origin, and evolution of viruses, as well as molecular mechanisms of virus–host interactions in archaea. He has published over 170 journal articles and serves as an editor or on the editorial boards of *Biology Direct*, *Research in Microbiology*, *Scientific Reports*, *Virology*, and *Virus Evolution*. He is also a member of the Executive Committee of the International Committee on Taxonomy of Viruses (ICTV) and chairs the Archaeal Viruses Subcommittee of the ICTV.

Maija Lappalainen, MD, PhD, Associate Professor of Clinical Microbiology, is the Head of Clinical Microbiology in the HUS Diagnostic Center, HUSLAB, University of Helsinki and Helsinki University Hospital, Helsinki, Finland. In her thesis during the years 1987–1992 she studied the incidence and diagnostics of congenital toxoplasmosis. After PhD, her research interest has been in diagnostic clinical virology, viral hepatitis, respiratory infections, viral infections in the immunocompromised patients and viral infections during pregnancy.

Hubert G.M. Niesters (1958) studied biology and chemistry in Nijmegen, the Netherlands. After obtaining his PhD in Utrecht (Prof. dr. M. Horzinek and Prof. dr. B. van der Zeijst, 1987) on the molecular epidemiology of infectious bronchitis virus, he worked as a post-doctoral fellow with Prof. dr. Jim Strauss at the California Institute of Technology (Pasadena, United States) on the replication of Alphaviruses. He received a Niels Stensen fellowship (The Netherlands) and an E.S. Gosney fellowship (Caltech) during this period.

After returning to the Netherlands (1989), he became a research associate in medical microbiology at the Diagnostic Medical Center (Delft) but moved back to clinical virology as a senior research associate in 1991 at the Erasmus University Medical Center Rotterdam (Head Prof. dr. Ab Osterhaus). From 1993 to 2007, he was responsible for the molecular diagnostics unit. During this period, he was involved in the discovery and characterization of several new viruses and variants. In 2007, he became full professor and director of the Laboratory of Clinical Virology within the Department of Medical Microbiology at the University Medical Center Groningen and University of Groningen.

He has been actively involved in the implementation and development of new technologies like real-time amplification and automation within clinical virology. He has been focusing on molecular diagnostics and its use and the clinical value in a transplant setting, as well as in monitoring treatment of hepatitis viruses. Recently, his interest focuses on rapid regional epidemiology, automation including MiddleWare solutions for molecular diagnostics, as well as the cost-benefit of rapid point-of-impact molecular testing. Special interest is focused on raising awareness for the detection of enteroviruses (enterovirus D68) and its relationship with acute flaccid myelitis (AFM).

Since 2017, he is the Chair of the executive board of QCMD (Quality Control of Molecular Diagnostics, Glasgow). He is an auditor and team leader for the Dutch Council of Accreditation and Co-Editor in Chief of the *Journal of Clinical Virology*. He is an (co)-author of more than 250 peer-reviewed papers, chapters and reviews including emerging viruses, such as enterovirus D68 and hepatitis E virus (H-index 80).

For his entire work, he received in 2016 the “Ed Nowakowski Senior Memorial Clinical Virology Award” from the Pan American Society for Clinical Virology.

Massimo Palmarini is the Director of the MRC-University of Glasgow Centre for Virus Research and Chair of Virology at the University of Glasgow, Glasgow, United Kingdom. A veterinarian by training, his research programs focus on the biology, evolution and pathogenesis of arboviruses and the mechanisms of virus cross-species transmission. His work is funded by the MRC and the Wellcome Trust. Massimo Palmarini has been elected Fellow of the Academy of Medical Sciences, of the Royal Society of Edinburgh and of the Royal Society of Biology and he was a Wolfson-Royal Society Research Merit Awardee. He is a Wellcome Trust Investigator.

David Prangishvili, PhD, Honorary Professor at the Institut Pasteur, Paris, France, and Professor at Tbilisi State University, Tbilisi, Georgia, is one of the pioneers in studies on the biology of Archaea and their viruses. His scientific career spans ex-USSR (Institute of Molecular Biology, Moscow; 1970–1976), Georgia (Georgian National Academy of Sciences, Tbilisi; 1976–1991), Germany (Max-Planck Institute for Biochemistry, Munich; University of Regensburg; 1991–2004) and France (Institut Pasteur, Paris, 2004–2020). In the research groups headed by him, several dozens of new species and eight new families of archaeal viruses have been discovered and characterized, which display remarkable diversity of unique morphotypes and exceptional genome contents. The results of his research contribute to the knowledge on viral diversity on our planet and change the field of prokaryotic virology, leading to the notion that viruses of

hyperthermophilic Archaea form a particular group in the viral world, distinctive from viruses of Bacteria and Eukarya, and to the recognition of the virosphere of Archaea as one of the distinct features of this Domain of Life. David Prangishvili is a member of the Academia Europaea, the European Academy of Microbiology, and the Georgian National Academy of Sciences.

David I. Stuart is MRC Professor of Structural Biology in the Nuffield Department of Medicine, Oxford University, Oxford, United Kingdom, Life Science Director at Diamond Light Source and Director of Instruct-ERIC (pan-European organisation providing shared access to infrastructure and methods for structural biology). He has diverse interests in structural virology from picornaviruses, double-stranded RNA viruses and enveloped RNA viruses. His drive to develop structural techniques led to the determination of the structure of Bluetongue virus (1995) and then the first membrane containing virus, PRD1. More recently, he has been at the fore-front of bringing Cryo-EM technology to bear on virus structure determination and its future role in visualizing virus function in cellulose. In addition to basic science he has a strong commitment to structural vaccinology and the development of antiviral drugs.

Dr. Nobuhiro Suzuki, PhD, received his MSc (1985) in phytopathology and PhD (1989) in virology from Tohoku University in Sendai, Japan. Dr. Suzuki currently serves as a full Professor of the Institute of Plant Stress and Resources, formerly Institute of Plant Sciences and Bioresources at Okayama University and as an Editor of *Virus Research*, *Frontiers in Virology*, *Journal of General Plant Pathology*, *Virology Journal*, and *Biology*. He has also been Guest Editor to *PLoS Pathogens*, *PNAS*, and *mBio*, and an Editorial Board member of *Virology* and *Journal of Virology*.

Suzuki Laboratory focuses on characterization of diverse viruses infecting phytopathogenic fungi and exploration of their interplays. Recent achievements include the discovery of a neo-virus lifestyle exhibited by a (+)ssRNA virus and an unrelated dsRNA virus in a plant pathogenic fungus and of multilayer antiviral defense in fungi involving Dicer. Prior to coming to Kurashiki, Okayama Prefecture, he was a visiting fellow of the Center for Agricultural Biotechnology at the

University of Maryland Biotechnology Institute (UMBI), College Park, MA, United States, for 4 years (1997–2001) to study molecular biology of hypoviruses in the laboratory of Professor Donald L. Nuss. Before visiting UMBI, he served as an assistant professor and a lecturer of the Biotechnology Institute at the Akita Prefectural College of Agriculture, Japan, for 11 years (1988–1998) where he was engaged in a project on molecular characterization of rice dwarf phytoecovirus, a member of the family *Reoviridae*. He received awards from the Japanese Phytopathological Society of Japan and Japanese Society for Virology for his outstanding achievements in plant and fungal virology.

FOREWORD

I am delighted to write the foreword to this wonderful Fourth Edition of the *Encyclopedia of Virology*. The Third Edition was published in 2008, how the world has changed in the intervening years. The release of the updated fourth edition could not be more timely or more prescient. It is superb and a huge tribute to the authors, Elsevier the publisher, and to the brilliant editors, Dennis Bamford and Mark Zuckerman.

SARS-CoV-2 has dominated the world since it emerged in 2019 and affected every continent and every aspect of life. A reminder, if it were needed, of the impact of infectious diseases, the importance of virology and the vulnerability and interconnectivity of our world.

There is no doubt that with rapidly changing ecology, urbanization, climate change, increased travel, and fragile public health systems, epidemics and pandemics will become more frequent, more complex and harder to prevent and contain. Most of these epidemics will be caused by viruses, those we know about and maybe able to predict and some we do not know of that will emerge from animals, plants or the environment. Our changing climate will change the epidemiology of viruses, their vectors and the infections they cause, hence the critical importance of this totally revised Fourth Edition of the *Encyclopedia of Virology* which brings together research and an understanding of viruses in animals, plants, bacteria and fungi, the environment, and among humans. Never has a holistic, one-health understanding been more important.

That starts with an understanding of the fundamentals of virology, a field of science that has been transformed in the years since the Third Edition. An understanding transformed by embracing traditional fields of molecular and structural biology, genomics, and influenced by immunology, genetics, pharmacology and increasingly by epidemiology and mathematics. Events of 2020 and 2021 also show why it is so important to integrate within traditional virology an understanding of the animal and human health and behavior, of climate change and its impact on the ecology of viruses, plant sciences and vectors. And why we must understand the viruses we think we know well, and those viruses less extensively studied. Research is critical to this, research that pushes the boundaries of what we know, has the humility to seek answers to things we do not understand and shares that knowledge with the widest possible community. That research will be most exciting at the interface between disciplines, most impactful when dynamic, open, inclusive, global, and collaborative.

This is what the Fourth Edition of the *Encyclopedia of Virology*, the largest reference source of research in virology sets out to achieve. It is a wonderful contribution to a critical field of knowledge. It contains new chapters, every chapter revised and updated by a dedicated global community who have come together to provide what is a brilliant and inspiring reference. It is an honor to contribute in a very small way to the timely release of the Fourth Edition of the *Encyclopedia of Virology*.

Jeremy Farrar

PREFACE

The fourth edition of the Encyclopedia of Virology is encyclopedic, but we wanted to move away from an alphabetical list, apart from where it was more logical, to a vision that encompassed a different structure. Articles describing novel trends as well as original discoveries in specific subfields of virology have been distributed into a set of five volumes, namely Fundamentals of Virology, Human and Animal Viruses, Plant Viruses, Bacterial, Archaeal, Fungal, Algal and Invertebrate Viruses, and Diagnosis, Treatment and Prevention of Virus Infections.

We had hoped that the new edition would 'go viral' but it was ironic that the time to publication 12 years after the previous edition had been made a bit longer due to a virus infection. The world encountered a devastating global pandemic, COVID-19, caused by a new type of a coronavirus, SARS-CoV-2. Scientists in many disciplines all over the world started immediate efforts to discover solutions as to how to mitigate and stop the spread of the pandemic. Virology moved from being a highly specialized subject to one in which everyone became a virologist, proving just how significant the different aspects of virology are in terms of understanding the nature of viral infection. Since the previous edition, the growth in the field of general virology has been enormous, including huge advances in basic science, identification of novel viruses, diagnostic methods, treatment and prevention. Taking this into account, the introduction of the articles within the Encyclopedia are very timely and crucial for providing a wealth of knowledge of the latest findings in the field of virology to a vast range of people, whether school students, undergraduates, postgraduates, teachers, scientists, researchers, journalists and others interested in infections and the conflict between the host and the pathogen.

Pandemic viruses have become a serious public concern in the changing world. We can ask ourselves whether we have reached the point in which nature can no longer cope with the consequences of increased population density and human activities that are harmful to the environment. Although several pandemics have threatened mankind before, this COVID-19 pandemic has highlighted the massive adverse economic consequences towards the wellbeing of society and the importance of research in virology.

We aimed to produce a Major Reference Work that differs in approach to others and binds all the virology disciplines together. Chapters have been included on origin, evolution and emergence of viruses, environmental virology and ecology, epidemiology, techniques for studying viruses, viral life cycles, structure, entry, genome and replication, assembly and packaging and taxonomy and viral–host interactions. Information has been included on all known species of viruses infecting bacteria, fungi, plants, vertebrates and invertebrates. Additional topics include antiviral classification and examples of their use in management of infection, diagnostic assays and vaccines, as well as the economic importance of viral diseases of crops and their control.

This edition used viral classification according to the 9th Report of the International Committee on Taxonomy of Viruses published in 2012. Updating it to the 10th Report in 2020 was affected by the pandemic and can be found online at <http://ictv.global/report/>.

We wish to acknowledge the hard work, interest, flexibility and patience, during such difficult times both socially and professionally, of everybody involved in the process of writing this edition of the Encyclopedia of Virology, especially Katarzyna Miklaszewska, Priscilla Braglia, Sam Crowe and colleagues at Elsevier. We sincerely thank all the authors and section editors for their excellent contributions to this edition.

Book Cover Image: Viruses are obligate parasites and all cells have their own viruses increasing the total number of viruses to the estimated astronomical number of 10^{31} that extends the number of stars in the universe. The viral string illustrates how pandemic viruses surround the globe. The original picture was created by Dr. Nina Atanasova (Finnish Meteorological Institute and University of Helsinki) and amended by Matthew Limbert at Elsevier.

*Dennis H. Bamford
Mark Zuckerman*

HOW TO USE THE ENCYCLOPEDIA

Structure of the Encyclopedia

All articles in the encyclopedia are arranged thematically as a series of entries within subjects/sections, apart from volume 2 where there it was more logical to have articles arranged alphabetically.

There are three features to help you easily find the topic you are interested in: a thematic contents list, a full subject index, and contributors.

1. Thematic contents list: The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia.
2. Index: The index appears at the end of volume 5 and includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.
3. Contributors: At the start of each volume there is a list of the authors who contributed to all volumes.

Georget Y. Reaiche-Miller
The University of Adelaide, Adelaide, SA, Australia

D.V.R. Reddy
International Crops Research Institute for the Semi-Arid Tropics, Hyderabad, India

Vishwanatha R.A.P. Reddy
The Pirbright Institute, Pirbright, United Kingdom

Juan Reguera
Aix-Marseille University, French National Center for Scientific Research, Marseille, France and French National Institute of Health and Medical Research, Marseille, France

William K. Reisen
University of California, Davis, CA, United States

Jingshan Ren
University of Oxford, Oxford, United Kingdom

Renato O. Resende
University of Brasilia, Brasilia, Brazil

Peter A. Revill
The Peter Doherty Institute of Infection and Immunity, Royal Melbourne Hospital, Melbourne, VIC, Australia

Félix A. Rey
Institut Pasteur, Paris, France

Lara Rheinemann
University of Utah, Salt Lake City, UT, United States

Simone G. Ribeiro
Embrapa Genetic Resources and Biotechnology, Brasília, Brazil

Daniel Rigling
Swiss Federal Institute for Forest, Snow and Landscape Research (WSL), Birmensdorf, Switzerland

Cristina Risco
Cell Structure Laboratory, National Center for Biotechnology – Spanish National Research Council (CNB-CSIC), Madrid, Spain

Efraín E. Rivera-Serrano

Lineberger Comprehensive Cancer Center, The University of North Carolina at Chapel Hill, NC, United States and Department of Microbiology and Immunology, The University of North Carolina at Chapel Hill, NC, United States

Cécile Robin

INRAE – French National Research Institute for Agriculture, Food and Environment, UMR BIOGECO, Cestas, France

Rodrigo A.L. Rodrigues

Federal University of Minas Gerais, Belo Horizonte, Brazil

Elina Roine

University of Helsinki, Helsinki, Finland

Maria R. Rojas

University of California, Davis, CA, United States

Marilyn J. Roossinck

Pennsylvania State University, State College, PA, United States

Vera I.D. Ros

Wageningen University and Research, Wageningen, The Netherlands

Cristina Rosa

Pennsylvania State University, University Park, PA, United States

Hanna Rose

Leibniz University Hannover, Hannover, Germany

David A. Rosenbaum

University of Florida, Gainesville, FL, United States

Shannan L. Rossi

The University of Texas Medical Branch, Galveston, TX, United States

Michael G. Rossmann[†]

Purdue University, West Lafayette, IN, United States

L. Roux

University of Geneva Medical School, Geneva, Switzerland

Simon Roux

US Department of Energy Joint Genome Institute, Walnut Creek, CA, United States

J. Rovnak

Colorado State University, Fort Collins, CO, United States

David J. Rowlands

University of Leeds, Leeds, United Kingdom

Polly Roy

Department of Pathogen Infection, Faculty of Infectious and Tropical Diseases, London School of Hygiene and Tropical Medicine, London, United Kingdom and University of Reading, Reading, United Kingdom

Aaron P. Roznowski

The University of Texas at Austin, Austin, TX, United States and University of Arizona, Tucson, AZ, United States

Luisa Rubino

Institute for Sustainable Plant Protection, National Research Council, Bari, Italy

Olli Ruuskanen

Turku University Hospital, Turku, Finland

Eugene V. Ryabov

USDA, Agricultural Research Service, Beltsville, MD, United States

Martin D. Ryan

University of St. Andrews, St. Andrews, United Kingdom

Ki H. Ryu

Seoul Women's University, Seoul, South Korea

Hanns-Joachim Rziha

Eberhard Karls University of Tübingen, Tübingen, Germany

Sead Sabanadzovic

Mississippi State University, Starkville, MS, United States

Roghayeh Safari

Cellular and Molecular Epigenetics (GIGA), Liège, Belgium and Molecular Biology (TERRA), Gembloux, Belgium

Azeez Sait Sahul Hameed

C. Abdul Hakeem College, Melvisharam, India

Nicole Samies

University of Alabama at Birmingham, Birmingham, AL, United States

Carmen San Martín

National Center for Biotechnology, Spanish National Research Council, Madrid, Spain

Ruth-Anne Sandaa

Department of Biological Sciences, University of Bergen, Bergen, Norway

Hélène Sanfaçon

Agriculture and Agri-Food Canada, Summerland, BC, Canada

[†]Deceased.

List of Contributors	xxi

VOLUME 1

The Virus as a Concept – Fundamentals of Virology

A Brief History of Virology <i>David J Rowlands</i>	3
The Origin of Viruses <i>Patrick Forterre and Morgan Gaïa</i>	14
The Virocell Concept <i>Patrick Forterre</i>	23
Virus Taxonomy <i>Jens H Kuhn</i>	28
The Greater Virus World and Its Evolution <i>Eugene V Koonin and Valerian V Dolja</i>	38
The Virus Species Concept <i>Peter Simmonds</i>	47
Genetic Diversity and Evolution of Viral Populations <i>Rafael Sanjuán and Pilar Domingo-Calap</i>	53
Mechanisms of RNA Virus Evolution <i>Lisa M Bono and Siobain Duffy</i>	62
Mechanisms of DNA Virus Evolution <i>Moriah L Szpara and Koenraad Van Doorslaer</i>	71
Paleovirology <i>Clément Gilbert</i>	79
Evolution Steered by Structure <i>Nicola GA Abrescia</i>	87

Pairwise Sequence Comparison in Virology <i>Tao Zhang, Zheng Gong, Tongkun Guo, Zhuang Xiong, and Yiming Bao</i>	100
Computational Analysis of Recombination in Viral Nucleotide Sequences <i>Miguel Arenas</i>	108
Phylogeny of Viruses <i>Alexander E Gorbalenya and Chris Lauber</i>	116
Virus Bioinformatics <i>Nikolaos Pappas, Simon Roux, Martin Hölzer, Kevin Lamkiewicz, Florian Mock, Manja Marz, and Bas E Dutilh</i>	124
Metagenomics in Virology <i>Simon Roux, Jelle Matthijnsens, and Bas E Dutilh</i>	133
Database and Analytical Resources for Viral Research Community <i>Sujal Phadke, Saichetana Macherla, and Richard H Scheuermann</i>	141
Classification of the Viral World Based on Atomic Level Structures <i>Janne J Ravantti and Nicola GA Abrescia</i>	153
Isolating, Culturing, and Purifying Viruses With a Focus on Bacterial and Archaeal Viruses <i>Katri Eskelin and Hanna M Oksanen</i>	162
High Throughput Sequencing and Virology <i>Graham L Freimanis and Nick J Knowles</i>	175
Single-Virus Genomics: Studying Uncultured Viruses, One at a Time <i>Manuel Martinez-Garcia, Francisco Martinez-Hernandez, and Joaquín Martínez Martínez</i>	184
Biophysical Characterizations in the Solution State <i>Robert P Rambo and Katsuaki Inoue</i>	191
Virus Crystallography <i>Jonathan M Grimes</i>	199
Advanced Light and Correlative Microscopy in Virology <i>Sergi Padilla-Parra, Charles A Coomer, and Irene Carlon-Andres</i>	208
Atomic Force Microscopy (AFM) Investigation of Viruses <i>Alexander McPherson</i>	218
Cryo-Electron Microscopy (CEM) Structures of Viruses <i>David Chmielewski and Wah Chiu</i>	233
Analysis of Viruses in the Cellular Context by Electron Tomography <i>Peijun Zhang and Luiza Mendonça</i>	242
Mathematical Modeling of Virus Architecture <i>Reidun Twarock</i>	248
Principles of Virus Structure <i>Madhumati Sevvana, Thomas Klose, and Michael G Rossmann[†]</i>	257
Structures of Small Icosahedral Viruses <i>Elizabeth E Fry, Jingshan Ren, and Claudine Porta</i>	278
Structural Principles of the Flavivirus Particle Organization and of Its Conformational Changes <i>Stéphane Duquerroy, Arvind Sharma, and Félix A Rey</i>	290
Reoviruses (Reoviridae) and Their Structural Relatives <i>Liya Hu, Mary K Estes, and B V Venkataram Prasad</i>	303

[†]Deceased.

Structures of Tailed Phages and Herpesviruses (<i>Herpesviridae</i>) <i>Montserrat Fàbrega-Ferrer and Miquel Coll</i>	318
Adenoviruses (<i>Adenoviridae</i>) and Their Structural Relatives <i>Gabriela N Condezo, Natalia Martín-González, Marta Pérez-Illana, Mercedes Hernando-Pérez, José Gallardo, and Carmen San Martín</i>	329
Negative Single-Stranded RNA Viruses (<i>Mononegavirales</i>): A Structural View <i>Juan Reguera</i>	345
Structure of Retrovirus Particles (<i>Retroviridae</i>) <i>David K Stammers and Jingshan Ren</i>	352
Structure of Helical Viruses <i>C Martin Lawrence</i>	362
Giant Viruses and Their Virophage Parasites <i>Rodrigo AL Rodrigues, Ana CdSP Andrade, Grazielle P Oliveira, and Jônatas S Abrahão</i>	372
Viral Replication Cycle <i>AJ Cann</i>	382
Viral Receptors <i>José M Casasnovas and Thilo Stehle</i>	388
Bacterial and Archeal Virus Entry <i>Minna M Poranen and Aušra Domanska</i>	402
Nonenveloped Eukaryotic Virus Entry <i>Ian M Jones and Polly Roy</i>	409
Enveloped Virus Membrane Fusion <i>Aurélié A Albertini and Yves Gaudin</i>	417
Genome Replication of Bacterial and Archaeal Viruses <i>Česlovas Venclovas</i>	429
Viral Transcription <i>David LV Bauer and Ervin Fodor</i>	439
Translation of Viral Proteins <i>Martin D Ryan and Garry A Luke</i>	444
Recombination <i>Jozef J Bujarski</i>	460
Assembly of Viruses: Enveloped Particles <i>CK Navaratnarajah, R Warriar, and RJ Kuhn</i>	468
Assembly of Viruses: Nonenveloped Particles <i>M Luo</i>	475
Virion Assembly: From Small Picornaviruses (<i>Picornaviridae</i>) to Large Herpesviruses (<i>Herpesviridae</i>) <i>Ling Zhu, Nan Wang, and Xiangxi Wang</i>	480
Genome Packaging <i>Richard J Bingham, Reidun Twarock, Carlos P Mata, and Peter G Stockley</i>	488
Virus Factories <i>Isabel Fernández de Castro, Raquel Tenorio, and Cristina Risco</i>	495
Release of Phages From Prokaryotic Cells <i>Jesse Cahill and Ry Young</i>	501
Virus Budding <i>Lara Rheinemann and Wesley I Sundquist</i>	519

Vesicle-Mediated Transcytosis and Export of Viruses <i>Efraín E Rivera-Serrano and Stanley M Lemon</i>	529
Vector Transmission of Animal Viruses <i>Houssam Attoui, Fauziah Mohd Jaafar, Rennos Fragkoudis, and Peter PC Mertens</i>	542
The Human Virome <i>Alexia Bordigoni, Sébastien Halary, and Christelle Desnues</i>	552
Epidemiology of Human and Animal Viral Diseases <i>Michael Edelstein</i>	559
Zoonosis, Emerging and Re-Emerging Viral Diseases <i>Janet M Daly</i>	569
Antiviral Innate Immunity: Introduction <i>Friedemann Weber</i>	577
Humoral and T Cell-Mediated Immunity to Viruses <i>Ane Ogbe and Lucy Dorrell</i>	584
Antigenicity and Antigenic Variation <i>Kuan-Ying A Huang, Xiaorui Chen, Che Ma, Dayna Cheng, Jen-Ren Wang, and Wan-Chun Lai</i>	597
Antigen Presentation <i>Andrew J McMichael</i>	601
Defense Against Viruses and Other Genetic Parasites in Prokaryotes <i>Kira S Makarova, Yuri I Wolf, and Eugene V Koonin</i>	606
Defective-Interfering Viruses <i>L Roux</i>	617
Ecology and Global Impacts of Viruses <i>Joanne B Emerson</i>	621
The Role of Retroviruses in Cellular Evolution <i>Andrea Kirmaier and Welkin E Johnson</i>	627
The Role of Bacteriophages in Bacterial Evolution <i>Chris M Rands and Harald Brüssow</i>	633
Viruses and Their Potential for Bioterrorism <i>Dana L Vanlandingham and Stephen Higgs</i>	644
The Use of Viral Promoters in Expression Vectors <i>Ian M Jones</i>	652
Oncolytic Viruses <i>Laura Burga and Mihnea Bostina</i>	658
Biotechnology Approaches to Modern Vaccine Design <i>George P Lomonosoff and Daniel Ponndorf</i>	662
Viruses: Impact on Science and Society <i>Neeraja Sankaran and Robin A Weiss</i>	671

VOLUME 2

Viruses as Infectious Agents: Human and Animal Viruses

Adenoviruses (<i>Adenoviridae</i>) <i>Balázs Harrach and Mária Benkő</i>	3
---	---

African Horse Sickness Virus (<i>Reoviridae</i>) <i>Piet A van Rijn</i>	17
African Swine Fever Virus (<i>Asfarviridae</i>) <i>Linda K Dixon, Rachel Nash, Philippa C Hawes, and Christopher L Netherton</i>	22
Akabane Virus and Schmallenberg Virus (<i>Peribunyaviridae</i>) <i>Martin Beer and Kerstin Wernike</i>	34
Alphaviruses Causing Encephalitis (<i>Togaviridae</i>) <i>Diane E Griffin</i>	40
Anelloviruses (<i>Anelloviridae</i>) <i>Fabrizio Maggi and Mauro Pistello</i>	48
Animal Lentiviruses (<i>Retroviridae</i>) <i>Esperanza Gomez-Lucia</i>	56
Animal Morbilliviruses (<i>Paramyxoviridae</i>) <i>Carina Conceicao and Dalan Bailey</i>	68
Animal Papillomaviruses (<i>Papillomaviridae</i>) <i>John S Munday</i>	79
Astroviruses (<i>Astroviridae</i>) <i>Virginia Hargest, Amy Davis, and Stacey Schultz-Cherry</i>	92
Avian Hepadnaviruses (<i>Hepadnaviridae</i>) <i>Allison R Jilbert, Georget Y Reaiche-Miller, and Catherine A Scougall</i>	100
Avian Herpesviruses (<i>Herpesviridae</i>) <i>Vishwanatha RAP Reddy and Venugopal Nair</i>	112
Avian Influenza Viruses (<i>Orthomyxoviridae</i>) <i>Nicolas Bravo-Vasquez and Stacey Schultz-Cherry</i>	117
Avian Leukosis and Sarcoma Viruses (<i>Retroviridae</i>) <i>Karen L Beemon</i>	122
Bluetongue Virus (<i>Reoviridae</i>) <i>Raghavendran Kulasegaran-Shylini and Polly Roy</i>	127
Borna Disease Virus and Related Bornaviruses (<i>Bornaviridae</i>) <i>Susan L Payne</i>	137
Bovine Leukemia Virus (<i>Retroviridae</i>) <i>Thomas Joris, Roghaiyeh Safari, Jean-Rock Jacques, and Luc Willems</i>	144
Bovine Viral Diarrhea, Border Disease, and Classical Swine Fever Viruses (<i>Flaviviridae</i>) <i>Paul Becher, Volker Moennig, and Norbert Tautz</i>	153
Capripoxviruses, Parapoxviruses, and Other Poxviruses of Ruminants (<i>Poxviridae</i>) <i>Philippa M Beard</i>	165
Chikungunya Virus (<i>Togaviridae</i>) <i>Thomas E Morrison and Stephanie E Ander</i>	173
Circoviruses (<i>Circoviridae</i>) <i>Giovanni Franzo and Joaquim Segalés</i>	182
Coronaviruses: General Features (<i>Coronaviridae</i>) <i>Paul Britton</i>	193
Coronaviruses: Molecular Biology (<i>Coronaviridae</i>) <i>X Deng and SC Baker</i>	198

Crimean-Congo Hemorrhagic Fever Virus and Nairoviruses of Medical Importance (<i>Nairoviridae</i>) <i>Ali Mirazimi, Felicity Burt, and Anna Papa</i>	208
Dengue Viruses (<i>Flaviviridae</i>) <i>Ashley L. St. John and Duane J. Gubler</i>	218
Ebola Virus (<i>Filoviridae</i>) <i>Andrea Marzi and Logan Banadyga</i>	232
Enteroviruses (<i>Picornaviridae</i>) <i>Carita Savolainen-Kopra, Soile Blomqvist, and Petri Susi</i>	245
Enveloped, Positive-Strand RNA Viruses (<i>Nidovirales</i>) <i>L. Enjuanes, AE Gorbalenya, RJ de Groot, JA Cowley, J Ziebuhr, and EJ Snijder</i>	256
Epstein-Barr Virus (<i>Herpesviridae</i>) <i>Lawrence S. Young</i>	267
Equine Herpesviruses (<i>Herpesviridae</i>) <i>Gisela Soboll-Hussey, Nikolaus Osterrieder, and Walid Azab</i>	278
Equine, Canine, and Swine Influenza (<i>Orthomyxoviridae</i>) <i>Janet M. Daly and Japhette E. Kembou-Ringert</i>	287
Feline Calicivirus (<i>Caliciviridae</i>) <i>Margaret J. Hosie and Michaela J. Conley</i>	294
Feline Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>Brian J. Willett and Margaret J. Hosie</i>	300
Fish and Amphibian Alloherpesviruses (<i>Herpesviridae</i>) <i>Maxime Boutier, Léa Morvan, Natacha Delrez, Francesco Origi, Andor Doszpoly, and Alain Vanderplasschen</i>	306
Fish Retroviruses (<i>Retroviridae</i>) <i>TA Paul, RN Casey, PR Bowser, JW Casey, J Rovnak, and SL Quackenbush</i>	316
Fish Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Gael Kurath and David Stone</i>	324
Foot-and-Mouth Disease Viruses (<i>Picornaviridae</i>) <i>David J. Rowlands</i>	332
Fowlpox Virus and Other Avipoxviruses (<i>Poxviridae</i>) <i>Efstathios S. Giotis and Michael A. Skinner</i>	343
Hantaviruses (<i>Hantaviridae</i>) <i>Tarja Sironen and Antti Vaheri</i>	349
Henipaviruses (<i>Paramyxoviridae</i>) <i>Lin-Fa Wang and Danielle E. Anderson</i>	355
Hepatitis A Virus (<i>Picornaviridae</i>) <i>Andreas Dotzauer</i>	362
Hepatitis B Virus (<i>Hepadnaviridae</i>) <i>Peter Karayiannis</i>	373
Hepatitis C Virus (<i>Flaviviridae</i>) <i>Ralf Bartenschlager and Keisuke Tabata</i>	386
Hepeviruses (<i>Hepeviridae</i>) <i>Xiang-Jin Meng</i>	397
Herpes Simplex Virus 1 and 2 (<i>Herpesviridae</i>) <i>David M. Knipe and Richard Whitley</i>	404

History of Virology: Vertebrate Viruses <i>F Fenner</i>	414
Human Boca- and Protoparvoviruses (<i>Parvoviridae</i>) <i>Maria Söderlund-Venermo and Jianming Qiu</i>	419
Human Coronavirus-229E, -OC43, -NL63, and -HKU1 (<i>Coronaviridae</i>) <i>Ding X Liu, Jia Q Liang, and To S Fung</i>	428
Human Cytomegalovirus (<i>Herpesviridae</i>) <i>Edward S Mocarski</i>	441
Human Immunodeficiency Virus (<i>Retroviridae</i>) <i>Blaide Woodburn, Ann Emery, and Ronald Swanstrom</i>	460
Human Metapneumovirus (<i>Pneumoviridae</i>) <i>Antonella Casola, Matteo P Garofalo, and Xiaoyong Bao</i>	475
Human Norovirus and Sapovirus (<i>Caliciviridae</i>) <i>Sumit Sharma, Marie Hagbom, Lennart Svensson, and Johan Nordgren</i>	483
Human Papillomaviruses (<i>Papillomaviridae</i>) <i>Alison A McBride and Samuel S Porter</i>	493
Human Parainfluenza Viruses (<i>Paramyxoviridae</i>) <i>Elisabeth Adderson</i>	502
Human Pathogenic Arenaviruses (<i>Arenaviridae</i>) <i>Sheli R Radoshitzky and Juan C de la Torre</i>	507
Human Polyomaviruses (<i>Papillomaviridae</i>) <i>Melissa S Maginnis</i>	518
Human T-Cell Leukemia Virus-1 and -2 (<i>Retroviridae</i>) <i>Amanda R Panfil and Patrick L Green</i>	528
Infectious Bursal Disease Virus (<i>Birnaviridae</i>) <i>Daral J Jackwood</i>	540
Infectious Pancreatic Necrosis Virus (<i>Birnaviridae</i>) <i>Øystein Evensen</i>	544
Influenza A Viruses (<i>Orthomyxoviridae</i>) <i>Laura Kakkola, Niina Ikonen, and Ilkka Julkunen</i>	551
Influenza B, C and D Viruses (<i>Orthomyxoviridae</i>) <i>Thorsten Wolff and Michael Veit</i>	561
Jaagsiekte Sheep Retrovirus (<i>Retroviridae</i>) <i>James M Sharp, Marcelo De las Heras, Massimo Palmarini, and Thomas E Spencer</i>	575
Japanese Encephalitis Virus (<i>Flaviviridae</i>) <i>Sang-Im Yun and Young-Min Lee</i>	583
Kaposi's Sarcoma-Associated Herpesvirus (<i>Herpesviridae</i>) <i>Anne K Cordes and Thomas F Schulz</i>	598
Marburg and Ravn Viruses (<i>Filoviridae</i>) <i>Courtney Woolsey, Thomas W Geisbert, and Robert W Cross</i>	608
Measles Virus (<i>Paramyxoviridae</i>) <i>Roberto Cattaneo and Michael McChesney</i>	619
Molluscum Contagiosum Virus (<i>Poxviridae</i>) <i>Joachim J Bugert and Rosina Ehmann</i>	629

Mumps Virus (<i>Paramyxoviridae</i>) <i>Stephen A Winchester and Kevin E Brown</i>	634
Murine Leukemia and Sarcoma Viruses (<i>Retroviridae</i>) <i>George R Young and Kate N Bishop</i>	643
Newcastle Disease Virus (<i>Paramyxoviridae</i>) <i>Ben Peeters and Guus Koch</i>	648
Orthobunyaviruses (<i>Peribunyaviridae</i>) <i>Alyssa B Evans, Clayton W Winkler, and Karin E Peterson</i>	654
Parapoxviruses (<i>Poxviridae</i>) <i>Hanns-Joachim Rziha and Mathias Büttner</i>	666
Parechoviruses (<i>Picornaviridae</i>) <i>Sisko Tauriainen and Glyn Stanway</i>	675
Parvoviruses of Carnivores, and the Emergence of Canine Parvovirus (<i>Parvoviridae</i>) <i>Colin R Parrish, Ian EH Voorhees, and Susan L Hafenstein</i>	683
Polioviruses (<i>Picornaviridae</i>) <i>Philip D Minor</i>	688
Porcine Reproductive and Respiratory Syndrome Virus and Equine Arteritis Virus (<i>Arteriviridae</i>) <i>Jianqiang Zhang, Alan T Loynachan, Gregory W Stevenson, and Jeffrey J Zimmerman</i>	697
Prions of Vertebrates <i>Jonathan DF Wadsworth and John Collinge</i>	707
Pseudorabies Virus (<i>Herpesviridae</i>) <i>Thomas C Mettenleiter and Barbara G Klupp</i>	714
Rabbit Hemorrhagic Disease Virus and European Brown Hare Syndrome Virus (<i>Caliciviridae</i>) <i>Lorenzo Capucci, Patrizia Cavadini, and Antonio Lavazza</i>	724
Rabbit Myxoma Virus and the Fibroma Viruses (<i>Poxviridae</i>) <i>Peter J Kerr</i>	730
Rabies and Other Lyssaviruses (<i>Rhabdoviridae</i>) <i>Ashley C Banyard and Anthony R Fooks</i>	738
Respiratory Syncytial Virus (<i>Pneumoviridae</i>) <i>Tiffany King, Tiffany Jenkins, Supranee Chaiwatpongsakorn, and Mark E Peebles</i>	747
Rhinoviruses (<i>Picornaviridae</i>) <i>Matti Waris and Olli Ruuskanen</i>	757
Rift Valley Fever Virus and Other Phleboviruses (<i>Phenuiviridae</i>) <i>Tetsuro Ikegami</i>	765
Roseoloviruses: Human Herpesviruses 6A, 6B and 7 (<i>Herpesviridae</i>) <i>Katherine N Ward</i>	778
Rotaviruses (<i>Reoviridae</i>) <i>Juana Angel and Manuel A Franco</i>	789
Rubella Virus (<i>Picornaviridae</i>) <i>Annette Mankertz</i>	797
Saint Louis Encephalitis Virus (<i>Flaviviridae</i>) <i>William K Reisen, Lark L Coffey, Daniele M Swetnam, and Aaron C Brault</i>	805
Severe Acute Respiratory Syndrome (SARS) and Middle East Respiratory Syndrome (MERS) (<i>Coronaviridae</i>) <i>Joseph SM Peiris and Leo LM Poon</i>	814

Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) (<i>Coronaviridae</i>) <i>Malik Peiris</i>	825
Simian Immunodeficiency Virus (SIV) and HIV-2 (<i>Retroviridae</i>) <i>Phyllis J Kanki</i>	827
Sindbis Virus (<i>Togaviridae</i>) <i>Satu Kurkela</i>	837
Tick-Borne Encephalitis Virus (<i>Flaviviridae</i>) <i>Teemu Smura, Suvi Kuivanen, and Olli Vapalahti</i>	843
Transmissible Gastroenteritis Virus of Pigs and Porcine Epidemic Diarrhea Virus (<i>Coronaviridae</i>) <i>Qiang Liu and Volker Gerds</i>	850
Vaccinia Virus (<i>Poxviridae</i>) <i>Yan Xiang and Rebecca K Lane</i>	854
Varicella-Zoster Virus (<i>Herpesviridae</i>) <i>Jeffrey I Cohen</i>	860
Variola and Monkeypox Viruses (<i>Poxviridae</i>) <i>Lalita Priyamvada and Panayampalli S Satheshkumar</i>	868
Vesicular Stomatitis Virus and Bovine Ephemeral Fever Virus (<i>Rhabdoviridae</i>) <i>Peter J Walker and Robert B Tesh</i>	875
West Nile Virus (<i>Flaviviridae</i>) <i>Fengwei Bai and Elizabeth Ashley Thompson</i>	884
Yellow Fever Virus (<i>Flaviviridae</i>) <i>Ashley E Strother and Alan DT Barrett</i>	891
Zika Virus (<i>Flaviviridae</i>) <i>Nikos Vasilakis, Shannan L Rossi, Sasha R Azar, Irma E Cisneros, Cassia F Estofolete, and Mauricio L Nogueira</i>	899

VOLUME 3

Viruses as Infectious Agents: Plant Viruses

An Introduction to Plant Viruses <i>Roger Hull</i>	3
Emerging and Re-Emerging Plant Viruses <i>Sabrina Bertin, Francesco Faggioli, Andrea Gentili, Ariana Manglli, Anna Taglienti, Antonio Tiberini, and Laura Tomassoli</i>	8
Emerging Geminiviruses (<i>Geminiviridae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, and Muhammad Mubin</i>	21
Movement of Viruses in Plants <i>Manfred Heinlein</i>	32
Plant Antiviral Defense: Gene-Silencing Pathways <i>Vitantonio Pantaleo, Chikara Masuta, and Hanako Shimura</i>	43
Plant Resistance to Viruses: Engineered Resistance <i>Marc Fuchs</i>	52
Plant Resistance to Viruses: Natural Resistance Associated With Dominant Genes <i>Mandy Ravensbergen and Richard Kormelink</i>	60

Plant Resistance to Viruses: Natural Resistance Associated With Recessive Genes <i>Masayoshi Hashimoto, Kensaku Maejima, Yasuyuki Yamaji, and Shigetou Namba</i>	69
Plant Viral Diseases: Economic Implications <i>Basavaprabhu L Patil</i>	81
Retrotransposons of Plants <i>M-A Grandbastien</i>	98
Vector Transmission of Plant Viruses <i>Etienne Herrbach and Quentin Chesnais</i>	106
Viral Suppressors of Gene Silencing <i>Hernan Garcia-Ruiz</i>	116
Virus-Induced Gene Silencing (VIGS) <i>Xu Tengzhi, Ugrappa Nagalakshmi, and Savithramma P Dinesh-Kumar</i>	123
Alfalfa Mosaic Virus (<i>Bromoviridae</i>) <i>L Sue Loesch-Fries</i>	132
Alphaflexiviruses (<i>Alphaflexiviridae</i>) <i>Sergey Y Morozov and Alexey A Agranovsky</i>	140
Alphasatellites (<i>Alphasatellitidae</i>) <i>Rob W Briddon and Muhammad S Nawaz-ul-Rehman</i>	149
Amalgaviruses (<i>Amalgaviridae</i>) <i>Ioannis E Tzanetakis, Sead Sabanadzovic, and Rodrigo A Valverde</i>	154
Badnaviruses (<i>Caulimoviridae</i>) <i>Andrew DW Geering</i>	158
Banana Bunchy Top Virus (<i>Nanoviridae</i>) <i>John E Thomas</i>	169
Barley Yellow Dwarf Viruses (<i>Luteoviridae</i>) <i>Leslie L Domier</i>	176
Bean Common Mosaic Virus and Bean Common Mosaic Necrosis Virus (<i>Potyviridae</i>) <i>Ramon Jordan and John Hammond</i>	184
Bean Golden Mosaic Virus and Bean Golden Yellow Mosaic Virus (<i>Geminiviridae</i>) <i>Francisco M Zerbini and Simone G Ribeiro</i>	192
Beet Curly Top Virus (<i>Geminiviridae</i>) <i>Robert L Gilbertson, Tomas A Melgarejo, Maria R Rojas, William M Wintermantel, and John Stanley</i>	200
Beet Necrotic Yellow Vein Virus (<i>Benyviridae</i>) <i>Sebastian Liebe, Annette Niehl, Renate Koenig, and Mark Varrelmann</i>	213
Benyviruses (<i>Benyviridae</i>) <i>Annette Niehl, Sebastian Liebe, Mark Varrelmann, and Renate Koenig</i>	219
Betaflexiviruses (<i>Betaflexiviridae</i>) <i>Nobuyuki Yoshikawa and Hajime Yaegashi</i>	229
Betasatellites and Deltasatellites (<i>Tolecasatellitidae</i>) <i>Muhammad S Nawaz-ul-Rehman, Nazia Nahid, Muhammad Hassan, and Muhammad Mubin</i>	239
Bluner-, Cile-, and Higreviruses (<i>Kitaviridae</i>) <i>Diego F Quito-Avila, Juliana Freitas-Astúa, and Michael J Melzer</i>	247
Brome Mosaic Virus (<i>Bromoviridae</i>) <i>Guijuan He, Zhenlu Zhang, Preethi Sathanantham, Arturo Diaz, and Xiaofeng Wang</i>	252

Bromoviruses (<i>Bromoviridae</i>) <i>Jozef J Bujarski</i>	260
Bymoviruses (<i>Potyviridae</i>) <i>Annette Niehl and Frank Rabenstein</i>	268
Cacao Swollen Shoot Virus (<i>Caulimoviridae</i>) <i>Emmanuelle Muller</i>	274
Carmo-Like Viruses (<i>Tombusviridae</i>) <i>Miryam Pérez-Cañamás and Carmen Hernández</i>	285
Cassava Brown Streak Viruses (<i>Potyviridae</i>) <i>Basavaprabhu L Patil</i>	293
Cassava Mosaic Viruses (<i>Geminiviridae</i>) <i>James Legg and Stephan Winter</i>	301
Caulimoviruses (<i>Caulimoviridae</i>) <i>James E Schoelz and Mustafa Adhab</i>	313
Cheraviruses, Sadwaviruses and Torradoviruses (<i>Secoviridae</i>) <i>Toru Iwanami and René AA van der Vlugt</i>	322
Citrus Tristeza Virus (<i>Closteroviridae</i>) <i>Moshe Bar-Joseph, Scott J Harper, and William O Dawson</i>	327
Closteroviruses (<i>Closteroviridae</i>) <i>Marc Fuchs</i>	336
Comoviruses and Fabaviruses (<i>Secoviridae</i>) <i>George P Lomonossoff</i>	348
Cotton Leaf Curl Disease (<i>Geminiviridae</i>) <i>Nasim Ahmed, Imran Amin, and Shahid Mansoor</i>	355
Cowpea Mosaic Virus (<i>Secoviridae</i>) <i>George P Lomonossoff</i>	364
Cucumber Mosaic Virus (<i>Bromoviridae</i>) <i>Judith Hirsch and Benoît Moury</i>	371
Dianthovirus (<i>Tombusviridae</i>) <i>Kiwamu Hyodo and Masanori Kaido</i>	383
Endornaviruses (<i>Endornaviridae</i>) <i>Toshiyuki Fukuhara</i>	388
Fimoviruses (<i>Fimoviridae</i>) <i>Toufic Elbeaino and Michele Digiaro</i>	396
Furoviruses (<i>Virgaviridae</i>) <i>Annette Niehl and Renate Koenig</i>	405
Geminiviruses (<i>Geminiviridae</i>) <i>Jesús Navas-Castillo and Elvira Fiallo-Olivé</i>	411
Hordeiviruses (<i>Virgaviridae</i>) <i>Zhihao Jiang, Meng Yang, Yongliang Zhang, Andrew O Jackson, and Dawei Li</i>	420
Idaeoviruses (<i>Mayoviridae</i>) <i>Robert R Martin and Karen E Keller</i>	430
Ilarviruses (<i>Bromoviridae</i>) <i>Aaron Simkovich, Susanne E Kohalmi, and Aiming Wang</i>	439

Luteoviruses (<i>Luteoviridae</i>) <i>Leslie L Domier</i>	447
Machlomovirus and Panicoviruses (<i>Tombusviridae</i>) <i>Kay Scheets</i>	456
Maize Streak Virus (<i>Geminiviridae</i>) <i>Darren P Martin and Aderito L Monjane</i>	461
Nanoviruses (<i>Nanoviridae</i>) <i>Bruno Gronenborn and H Josef Vetten</i>	470
Necro-Like Viruses (<i>Tombusviridae</i>) <i>Luisa Rubino and Giovanni P Martelli[†]</i>	481
Nepoviruses (<i>Secoviridae</i>) <i>Hélène Sanfaçon</i>	486
Ophioviruses (<i>Aspiviridae</i>) <i>Anna M Vaira and John Hammond</i>	495
Orthospoviruses (<i>Tospoviridae</i>) <i>Renato O Resende and Hanu R Pappu</i>	507
Ourmiaviruses (<i>Botourmiaviridae</i>) <i>Gian Paolo Accotto and Cristina Rosa</i>	516
Papaya Ringspot Virus (<i>Potyviridae</i>) <i>Cécile Desbiez and Hervé Lecoq</i>	520
Pecluviruses (<i>Virgaviridae</i>) <i>Hema Masarapu, Pothur Sreenivasulu, Philippe Delfosse, Claude Bragard, Anne Legreve, and DVR Reddy</i>	528
Pepino Mosaic Virus (<i>Alphaflexiviridae</i>) <i>Rene AA van der Vlugt and CCMM Stijger</i>	539
Plant Reoviruses (<i>Reoviridae</i>) <i>Yu Huang and Yi Li</i>	545
Plant Resistance to Geminiviruses <i>Basavaprabhu L Patil, Supriya Chakraborty, Henryk Czosnek, Elvira Fiallo-Olivé, Robert L Gilbertson, James Legg, Shahid Mansoor, Jesús Navas-Castillo, Rubab Z Naqvi, Saleem U Rahman, and Francisco M Zerbini</i>	554
Plant Rhabdoviruses (<i>Rhabdoviridae</i>) <i>Ralf G Dietzgen, Michael M Goodin, and Zhenghe Li</i>	567
Plant Satellite Viruses (<i>Albetovirus, Aumaivirus, Papanivirus, Virtovirus</i>) <i>Mart Krupovic</i>	581
Plum Pox Virus (<i>Potyviridae</i>) <i>Miroslav Glasa and Thierry Candresse</i>	586
Poleroviruses (<i>Luteoviridae</i>) <i>Hernan Garcia-Ruiz, Natalie M Holste, and Katherine LaTourrette</i>	594
Pomoviruses (<i>Virgaviridae</i>) <i>Eugene I Savenkov</i>	603
Potato Virus Y (<i>Potyviridae</i>) <i>Laurent Glais and Benoît Moury</i>	612
Potexviruses (<i>Alphaflexiviridae</i>) <i>Ki H Ryu, Eun G Song, and Jin S Hong</i>	623

[†]Deceased.

Potyviruses (<i>Potyviridae</i>) <i>Adrián Valli, Juan A García, and Juan J López-Moya</i>	631
Quinviruses (<i>Betaflexiviridae</i>) <i>Ki H Ryu and Eun G Song</i>	642
Reverse-Transcribing Viruses (<i>Belpaoviridae, Metaviridae, and Pseudoviridae</i>) <i>Carlos Llorens, Beatriz Soriano, Maria A Navarrete-Muñoz, Ahmed Hafez, Vicente Arnau, Jose Miguel Benito, Toni Gabaldon, Norma Rallon, Jaume Pérez-Sánchez, and Mart Krupovic</i>	653
Rice Tungro Disease (<i>Secoviridae, Caulimoviridae</i>) <i>Gaurav Kumar, Fauzia Zarreen, and Indranil Dasgupta</i>	667
Rice Yellow Mottle Virus (<i>Solemoviridae</i>) <i>Eugénie Hébrard, Nils Poulicard, and Mbolarinosy Rakotomalala</i>	675
Satellite Nucleic Acids and Viruses <i>Olufemi J Alabi, Alfredo Diaz-Lara, and Maher Al Rwahnih</i>	681
Secoviruses (<i>Secoviridae</i>) <i>Jeremy R Thompson</i>	692
Sequiviruses and Waikaviruses (<i>Secoviridae</i>) <i>Lucy Rae Stewart</i>	703
Solemoviruses (<i>Solemoviridae</i>) <i>Cecilia Sarmiento, Merike Sõmera, and Erkki Truve[†]</i>	712
Tenuiviruses (<i>Phenuiviridae</i>) <i>Bertha Cecilia Ramirez and Anne-Lise Haenni</i>	719
Tobacco Mosaic Virus (<i>Virgaviridae</i>) <i>Marc HV Van Regenmortel</i>	727
Tobamoviruses (<i>Virgaviridae</i>) <i>Ulrich Melcher, Dennis J Lewandowski, and William O Dawson</i>	734
Tobraviruses (<i>Virgaviridae</i>) <i>Stuart A MacFarlane</i>	743
Tomato Leaf Curl New Delhi Virus (<i>Geminiviridae</i>) <i>Supriya Chakraborty and Manish Kumar</i>	749
Tomato Spotted Wilt Virus (<i>Tospoviridae</i>) <i>Hanu R Pappu, Anna E Whitfield, and Athos S de Oliveira</i>	761
Tomato Yellow Leaf Curl Viruses (<i>Geminiviridae</i>) <i>Henryk Czosnek</i>	768
Tombusvirus-Like Viruses (<i>Tombusviridae</i>) <i>K Andrew White</i>	778
Tombusviruses (<i>Tombusviridae</i>) <i>Luisa Rubino and Kay Scheets</i>	788
Tritimoviruses and Rymoviruses (<i>Potyviridae</i>) <i>Satyanarayana Tatineni and Gary L Hein</i>	797
Triviruses (<i>Betaflexiviridae</i>) <i>Yahya ZA Gaafar and Heiko Ziebell</i>	805
Tymoviruses (<i>Tymoviridae</i>) <i>Rosemarie W Hammond and Peter Abrahamian</i>	818

[†]Deceased.

Umbraviruses (<i>Tombusviridae</i>) <i>Eugene V Ryabov and Michael E Taliansky</i>	827
Varicosaviruses (<i>Rhabdoviridae</i>) <i>Takahide Sasaya</i>	833
Virgaviruses (<i>Virgaviridae</i>) <i>Eugene I Savenkov</i>	839
Viroids (<i>Pospiviroidae</i> and <i>Avsunviroidae</i>) <i>Ricardo Flores and Robert A Owens</i>	852
Watermelon Mosaic Virus and Zucchini Yellow Mosaic Virus (<i>Potyviridae</i>) <i>Cécile Desbiez and Hervé Lecoq</i>	862

VOLUME 4

Viruses as Infectious Agents: Bacterial, Archaeal, Fungal, Algal, and Invertebrate Viruses

Bacterial Viruses

History of Virology: Bacteriophages <i>William C Summers</i>	3
Icosahedral Phages – Single-Stranded DNA (ϕ X174) <i>Bentley A Fane and Aaron P Roznowski</i>	10
Single-Stranded RNA Bacterial Viruses <i>Peter G Stockley and Junjie Zhang</i>	21
Enveloped Icosahedral Phages – Double-Stranded RNA (ϕ 6) <i>Paul Gottlieb and Aleksandra Alimova</i>	26
Membrane-Containing Icosahedral DNA Bacteriophages <i>Roman Tuma, Sarah J Butcher, and Hanna M Oksanen</i>	36
Tailed Double-Stranded DNA Phages <i>Robert L Duda</i>	45
Helical and Filamentous Phages <i>Andreas Kuhn and Sebastian Leptihn</i>	53
Replication of <i>Bacillus</i> Double-Stranded DNA Bacteriophages <i>Silvia Ayora, Paulo Tavares, Ruben Torres, and Juan C Alonso</i>	61
Lytic Transcription <i>William McAllister and Deborah M Hinton</i>	69
Lysogeny <i>Keith E Shearwin and Jia Q Truong</i>	77
Decision Making by Temperate Phages <i>Ido Golding, Seth Coleman, Thu VP Nguyen, and Tianyou Yao</i>	88
Mobilization of Phage Satellites <i>Kristen N LeGault and Kimberley D Seed</i>	98
Portal Vertex <i>Peng Jing and Mauricio Cortes Jr.</i>	105

Prohead, the Head Shell Pre-Cursor <i>Marc C Morais and Michael E Woodson</i>	115
Enzymology of Viral DNA Packaging Machines <i>Carlos E Catalano</i>	124
DNA Packaging: DNA Recognition <i>Sandra J Greive and Oliver W Bayfield</i>	136
DNA Packaging: The Translocation Motor <i>Janelle A Hayes and Brian A Kelch</i>	148
Biophysics of DNA Packaging <i>Joshua Pajak, Gaurav Arya, and Douglas E Smith</i>	160
Energetics of the DNA-Filled Head <i>Alex Evilevitch</i>	167
Bacteriophage Receptor Proteins of Gram-Negative Bacteria <i>Sarah M Doore, Kristin N Parent, Sundharraman Subramanian, Jason R Schrad, and Natalia B Hubbs</i>	175
Tail Structure and Dynamics <i>Shweta Bhatt, Petr G Leiman, and Nicholas MI Taylor</i>	186
Bacteriophage Tail Fibres, Tailspikes, and Bacterial Receptor Interaction <i>Mateo Seoane-Blanco, Mark J van Raaij, and Meritxell Granell</i>	194
Phage Genome and Protein Ejection In Vivo <i>Ian J Molineux, L Letti Lopez, and Aaron P Roznowski</i>	206
Dealing With the Whole Head: Diversity and Function of Capsid Ejection Proteins in Tailed Phages <i>Lindsay W Black and Julie A Thomas</i>	219
Jumbo Phages <i>Isaac T Younker and Carol Duffy</i>	229
CRISPR-Cas Systems and Anti-CRISPR Proteins: Adaptive Defense and Counter-Defense in Prokaryotes and Their Viruses <i>Asma Hatoum-Aslan and Olivia G Howell</i>	242
Bacteriophage: Therapeutics and Diagnostics Development <i>Teng-Chieh Yang</i>	252
Bacteriophage Vaccines <i>Pan Tao and Venigalla B Rao</i>	259
Bacteriophage Diversity <i>Julianne H Grose and Sherwood R Casjens</i>	265
Genetic Mosaicism in the Tailed Double-Stranded DNA Phages <i>Welkin H Pope</i>	276
Bacteriophages of the Human Microbiome <i>Pilar Manrique, Michael Dills, and Mark J Young</i>	283
Bacteriophage: Red Recombination System and the Development of Recombineering Technologies <i>Lynn C Thomason and Kenan C Murphy</i>	291
Nanotechnology Application of Bacteriophage DNA Packaging Nanomotors <i>Tao Weitao, Lixia Zhou, Zhefeng Li, Long Zhang, and Peixuan Guo</i>	302
General Ecology of Bacteriophages <i>Stephen T Abedon</i>	314
Marine Bacteriophages <i>Vera Bischoff, Falk Zucker, and Cristina Moraru</i>	322

Ecology of Phages in Extreme Environments <i>Tatiana A Demina and Nina S Atanasova</i>	342
---	-----

Archaeal Viruses

Diversity of Hyperthermophilic Archaeal Viruses <i>David Prangishvili, Mart Krupovic, and Diana P Baquero</i>	359
Euryarchaeal Viruses <i>Tatiana A Demina and Hanna M Oksanen</i>	368
Vesicle-Like Archaeal Viruses <i>Elina Roine and Nina S Atanasova</i>	380
Virus–Host Interactions in Archaea <i>Diana P Baquero, David Prangishvili, and Mart Krupovic</i>	387
Antiviral Defense Mechanisms in Archaea <i>Qunxin She</i>	400
Discovery of Archaeal Viruses in Hot Spring Environments Using Viral Metagenomics <i>Jennifer Wirth, Jacob H Munson-McGee, and Mark J Young</i>	407
Metagenomes of Archaeal Viruses in Hypersaline Environments <i>Fernando Santos, María D Ramos-Barbero, and Josefa Antón</i>	414
Extreme Environments as a Model System to Study How Virus–Host Interactions Evolve Along the Symbiosis Continuum <i>Samantha J DeWerff and Rachel J Whitaker</i>	419

Fungal Viruses

An Introduction to Fungal Viruses <i>Nobuhiro Suzuki</i>	431
Cross-Kingdom Virus Infection <i>Liyang Sun, Hideki Kondo, and Ida Bagus Andika</i>	443
Diversity of Mycoviruses in Aspergilli <i>Ioly Kotta-Loizou</i>	450
Evolution of Mycoviruses <i>Mahtab Peyambari, Vaskar Thapa, and Marilyn J Roossinck</i>	457
Mixed Infections of Mycoviruses in Phytopathogenic Fungus <i>Sclerotinia sclerotiorum</i> <i>Jiatao Xie and Daohong Jiang</i>	461
Mycovirus-Mediated Biological Control <i>Daniel Rigling, Cécile Robin, and Simone Prospero</i>	468
Mycoviruses With Filamentous Particles <i>Michael N Pearson</i>	478
Prions of Yeast and Fungi <i>Reed B Wickner and Herman K Edskes</i>	487
Single-Stranded DNA Mycoviruses <i>Daohong Jiang</i>	493
Structure of Double-Stranded RNA Mycoviruses <i>José R Castón, Nobuhiro Suzuki, and Said A Ghabrial[†]</i>	504

[†]Deceased.

<i>Ustilago maydis</i> Viruses and Their Killer Toxins <i>Alexis Williams and Thomas J Smith</i>	513
Vegetative Incompatibility in Filamentous Fungi <i>Songsong Wu, Daohong Jiang, and Jiatao Xie</i>	520
Viral Diseases of <i>Agaricus bisporus</i> , the Button Mushroom <i>Kerry S Burton and Greg Deakin</i>	528
Viral Killer Toxins <i>Manfred J Schmitt and Björn Becker</i>	534
Alternaviruses (Unassigned) <i>Hiromitsu Moriyama, Nanako Aoki, Kuko Fuke, Kana Takeshita Urayama, Naoki Takeshita, and Chien-Fu Wu</i>	544
Barnaviruses (Barnaviridae) <i>Peter A Revill</i>	549
Botybirnaviruses (Botybirnavirus) <i>Mingde Wu, Guoqing Li, Daohong Jiang, and Jiatao Xie</i>	552
Chrysoviruses (Chrysoviridae) - General Features and Chrysovirus-Related Viruses <i>Ioly Kotta-Loizou, Robert HA Coutts, José R Castón, Hiromitsu Moriyama, and Said A Ghabrial[†]</i>	557
Fungal Partitiviruses (Partitiviridae) <i>Eeva J Vainio</i>	568
Fusariviruses (Unassigned) <i>Sotaro Chiba</i>	577
Giardiavirus (Totiviridae) <i>Juliana Gabriela Silva de Lima, João Paulo Matos Santos Lima, and Daniel Carlos Ferreira Lanza</i>	582
Hypoviruses (Hypoviridae) <i>Dong-Xiu Zhang and Donald L Nuss</i>	589

BACTERIAL VIRUSES

History of Virology: Bacteriophages

William C Summers, Yale University, New Haven, CT, United States

© 2021 Elsevier Ltd. All rights reserved.

This is an update of H.-W. Ackermann, History of Virology: Bacteriophages, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00590-2.

Discovery of Phages

Although bacteriophages are the most abundant organisms on our planet, and they often exert drastic effects (lysis) on their bacterial hosts, it was not until the second decade of the 20th century that they were recognized and their basic biological nature was studied. While the literature contains several dozen reports that may be, only in retrospect, of phenomena associated with bacteriophages, the first clear recognition and description of what was at the time called “the bacteriophage phenomenon” was by a rather mysterious French-Canadian autodidact, Félix Hubert d’Herelle. D’Herelle, working at the Pasteur Institute during the first world war, was investigating the problem of virulence of bacterial strains. The basis for differing virulence of different isolates of the same bacterial species was of both theoretical and practical interest. Basing his reasoning on earlier (later shown to be incorrect) ideas that microbial virulence was modulated by “associated” organisms, d’Herelle fractionated a bacterial culture from a particularly virulent outbreak of dysentery by filtration to obtain a bacteria-free filtrate that he added back to a pure culture of the original organism. To his surprise, rather than increase the virulence of this culture, this filtrate caused lysis of the bacterial culture and, on solid media, the bacterial growth was inhibited in small spots. Material recovered from the spots was sterile with respect to bacteria, but could cause sequential lysis of fresh cultures. This “lytic principle” could be serially propagated indefinitely. D’Herelle reasoned that this “lytic principle” was a filter-passing, particulate agent that could multiply at the expense of the bacterial cell. He called it “bacteriophage” and classed as an “ultravirus”, meaning that it was smaller than the usual “virus”, a term used at the time to indicate any agent of transmissible disease. In his words, bacteriophage was an invisible obligate parasite.

D’Herelle was more expansive than just describing a new type of microbe, however. Since the bacteriophage was able to kill bacteria, and it appeared to him that the quantity of bacteriophage in patient samples increased as the patient was recovering, he reasoned that the recovery itself was caused by the takeover by the bacteriophage. Again, in his words, it was the agent of recovery and immunity. In the pre-antibiotic era this concept promised here-to-fore unavailable opportunities to treat infectious diseases.

Almost immediately after d’Herelle’s initial report in 1917 and his assertion that phages were involved in recovery from infectious diseases as well as the agent of what he called natural immunity, his discovery was explored by others and controversy ensued. The initial controversy concerned the biological nature of phage, that is, was it an ultravirus or a cellular product? This controversy became acute when d’Herelle challenged the theory of immunity recently advocated by the eminent director of the Pasteur Institute in Brussels, and recent Nobel prize winner, Jules Bordet. In his 1923 monograph on phage and disease, d’Herelle referred to Bordet’s work on bacteriolytic antibodies as “an error”. Bordet and his young protégé, Andre Gratia, took up the challenge, initially not defending the antibody work, but by attacking d’Herelle’s interpretation of the nature of phage. This approach was of little effect, so when they discovered Twort’s rather obscure paper on ultra-microscopic viruses from 1915, Bordet and Gratia launched an attack on d’Herelle’s priority of discovery. This dispute was intense for almost a decade, and probably was a deterrent and distraction to phage research for several decades. The priority dispute survives to the present.

D’Herelle’s response to the priority challenge was to try to demonstrate that what he had discovered was not the same phenomenon as observed by Twort. This work did help to clarify the nature of phage but did not convince most observers for the simple reasons that Twort’s paper was vague and he published nothing later in the way of clarifying experiments.

Two key problems were at the center of d’Herelle’s work on the nature of phage in the 1920s: is phage a unique organism that shows various manifestations, or are there many species of phage? D’Herelle argued for the “unicity” of phage, and claimed that under different conditions, for example, when supplied with different host bacteria, it adapted to such changes. This notion was not so strange as it seems today. In the 19th century, bacteriologists argued the same way about bacterial species, one species with variable forms (polymorphism) or many species, each with a stable form (monomorphism). Also, in the 1920s, a theory called “cyclogeny” was popular that suggested microbial cultures could change form and behavior depending on cultural conditions. Examples include bacterial shape changes observed in exponentially growing cultures versus stationary phase cultures and changes observed upon bacterial sporulation and germination.

The second key problem involved the physical nature of phage. D’Herelle argued that the fact that phage produced plaques, and that the number of plaques produced upon dilution followed a Poisson distribution, proved that phage were particulate in nature. He even enlisted Einstein, with whom he discussed the matter, on his side in the argument: “I was very glad to see how this deservedly-famous mathematician evaluated my experimental demonstration, for I do not believe that there are a great many biological experiments whose nature satisfies a mathematician”. Still, most bacteriologists of the day thought of phage as some

sort of cellular product with lytic properties, such as the recently discovered enzyme, lysozyme. The “corpuscular nature of phage” was not definitively settled until they were visualized by electron microscopy in 1939.

A third controversy that smoldered for many years surrounded the status of phages (and filterable viruses in general) was their status as “living” beings. Microbiologists in particular struggled with various definitions of “life”, probably a legacy of earlier vitalism. While viruses seemed to “reproduce”, which was one key property of living things, it was not clear that they could “assimilate” material from their environment in order to grow. Their dependence on a full-fledged cellular host was confusing in terms of the existing criteria for “life”. At this period, autocatalytic enzymes such as pepsinogen and trypsinogen, which could convert themselves from inactive to active pepsin and trypsin, were discovered. Could phage “growth” be such an autocatalytic phenomenon? Nobelist John Northrop and his colleagues in the Rockefeller Virus Unit at Princeton thought so.

Biologists were intrigued by things “at the borderline of life”. D’Herelle even developed an extensive theory of evolution based on phage as the chemical basis for life, asserting that phage were a colloidal form of matter that coalesced into protoplasm and cells. He undertook a search for phages in sulfur hot springs and other places where the “origin of life” might have occurred. He termed the study of phage “protobiology” and assigned the Linnaean binomial *Bacteriophagus protobius* early in his work on “protobes”. Indeed, during his tenure at Yale in the late 1920s and early 1930s, he referred to himself as Professor of Protobiology. The question of the organismal nature of viruses led scientists such as Jacques Bronfenbrenner to examine the respiration of phages using techniques such as the newly devised Warburg apparatus. To add to the mystery of viruses, in 1935 Wendell Stanley managed to obtain viruses in crystalline form, the *sine qua non* of chemical purity. Stanley’s chemical analysis of the crystals of tobacco mosaic virus found them to be made of protein (he missed the 7% phosphorus content, an indication of the presence of nucleic acid, later found by Bawden and Pirie in 1936). The question of whether viruses are “living or dead” has by now been relegated to late night undergraduate debating, and in 1957, Andre Lwoff simply stated “viruses are viruses”.

Phage Therapy

One of d’Herelle’s earliest observations of phage involved dysentery patients and he noted the quantity and virulence of the phages in stool samples seemed to increase as the patients were recovering from the disease. This, as noted above, suggested that the phage was contributing to the recovery. It was no big leap to suggest that phages, isolated in the laboratory, might be used as treatment of such diseases. In the era before antibiotics, such therapeutic potential generated great interest, and the interest in phage in the decades of the 1920s and 1930s focused mainly on various attempts to exploit this therapeutic promise.

The first trials of phage therapy were carried out in the veterinary setting. D’Herelle carried out a trial of phages in an epidemic of avian typhosis, a bacterial disease of chickens, that was becoming endemic in rural France in 1918. He isolated a phage that was virulent against the pathogen as isolated from the diseased birds, and in both field trials and laboratory tests, found that phage had both therapeutic and prophylactic usefulness in actual disease outbreaks. He continued his search for opportunities to field-test his ideas and became a veritable globe trotter in this endeavor, spreading phages in North Africa, Argentina, French Indochina, India, and Egypt, as well as the hospitals of Paris. In the pre-antibiotic era, his work attracted much attention and many attempts to employ phage therapy. After over a decade of clinical experience, the American Medical Association’s Council on Pharmacy and Chemistry reviewed the literature on phage therapy and the 1934 report written by Monroe Eaton and Stanhope Bayne-Jones concluded that the efficacy of phage therapy was still not established because of the conflicting reports, ambiguous results, and lack of understanding of the biological nature of phage. This report coincided with d’Herelle’s departure from the US to set up a phage institute in Tbilisi in the USSR, an ill-fated venture that ended with his return to France in 1937 after the execution of his host and fellow phage worker, Georgi Eliava, who was caught up in the Stalinist purges of that period. This tragedy, shortly followed by the events leading up to World War 2, curtailed the influence of the most ardent and effective advocate of phage therapy. The discovery and effectiveness of antibiotics (and chemotherapy such as the sulfa drugs) in the late 1930s and on into the next decade led to the eclipse of interest in phage therapy, especially in the West.

In the Eastern Bloc of nations, partly because of the difficulty in developing the capacity to produce antibiotics and partly because of the lingering interest in phage therapy, research on phage therapy continued in several places, especially in Tbilisi and Poland. As understanding of phage biology increased, these centers profited from new knowledge as applied to phage therapy and have emerged in recent years as leaders in the renewed interest in phage therapy in this era of multi-drug antibiotic resistance.

By the mid-1980s, especially with the widespread recognition of MRSA and the ubiquity of horizontal gene transmission of drug-resistance, the search for solutions to this problem became acute. New antibiotic discovery was recognized as both economically non-viable as well as likely to be futile. Phage therapy was again seriously considered. In the West phage therapy seemed to have been discarded for two reasons, one theoretical and one political. Since phages were known to be antigenic, the development of immune resistance was considered a fatal drawback as was the well-known ability of bacteria to mutate to phage resistance. Further, cold-war ideology militated against any recognition of scientific work from the Soviets. A key study leading to the resurgence of interest in phage therapy was published in 1996 by Carl Merrill and his colleagues, who showed that the problem of immune clearance of therapeutic phages was not insurmountable. They showed that by repeated cycles of selection *in vivo*, phages strains (of Lambda bacteriophage) could be derived that were invisible to the host (mouse) immune recognition system. Detailed understanding of the nature of phage receptors and phage resistance mechanisms suggested that these were not such daunting impediments. By 2000, phage therapy had become respectable again.

Phage Typing

Soon after the discovery of bacteriophages by d'Herelle in 1917, it became clear that there was some sort of specificity of phages for particular host strains of bacteria. While the issue of "unicity" of phage was unresolved, it was still observed that phage isolates could be obtained (whether by adaptation or by isolation of pre-existing strains) that could distinguish between different bacterial hosts by their "host range". D'Herelle and his colleagues noted some correlation between phage strains and the immunological properties of the host bacteria. Other phage researchers, especially James Craigie in Canada, inverted this notion to devise phage strains that could be used to classify bacterial based on their susceptibility to known tester phage strains. Classification of the *Salmonellae* was a particularly fraught problem, and in 1938, Yen and Craigie published a landmark classification of *S. typhi* (*B. typhosus*) by a set of "typing phages" that had host ranges that correlated precisely with the Vi surface antigen types. Phage typing became a widespread technique in diagnostic bacteriology and epidemiological investigations, yet it also remained a distinct branch of phage research. Phages were isolated and characterized for their utility in discriminating one bacterial variant from another, and standard sets of phages were developed for microbiological reference laboratories. Phage typing continues as a useful and reliable tool in diagnostic bacteriology even today. Phage typing is relatively rapid, easy, and low tech, and the diversity of phages has made it possible to find phages with the needed fine discriminatory properties. Interestingly, phage typing was, and continues to be, successful even though its practitioners and developers have been rather separate from the basic phage researchers who were attacking the fundamental biology of bacteriophages.

Phage Genetics

The very first defining property of phages was their serial transmissibility, a property that implied some sort of heredity mechanism. Indeed, as H.J. Muller famously noted in 1922, "if these d'Herelle bodies were really genes, fundamentally like our chromosome genes, they would give us an utterly new angle from which to attack the gene problem". The hereditary properties of phage were understood only slowly, partly because the concepts of adaptation, mutation, and speciation were just being extended to the microbial world. By the mid-1930s it was becoming clear that certain observable characters of viruses, such as host range and lesion morphology, behaved as stable, heritable properties. This was as true for phages as for animal and plant viruses.

One oddity that phage presented was the ability of some phages to associate with their host bacteria in mysterious ways that at times appeared to be a kind of latency (later termed the lysogenic state) and at times appeared to be a kind of genetic modifier that changed one of more bacterial property, for example, toxin production or surface antigens (later termed phage conversion or phage transduction). The debates over the biologic nature of phage (microbe or self-activating enzyme) hampered the clarification of the genetic nature of phage biology.

In the 1930s, Eugene and Elizabeth Wollman at the Pasteur Institute advanced the understanding of the lysogenic state and the relationship of phage infection to the introduction of new genes into the host cells. In the immediate post-war period with a renewed interest in the fundamental biology of phage (as opposed to their potential as anti-infectious agents for therapy) several groups saw the utility of phages as simple genetic organisms analogous to other microbes such as bacteria and fungi. Different "strains" of phage had been isolated from the earliest research that differed in their size, host range, and plaque appearance on a uniform "lawn" of a given host. Further, it was noted that rare variants arose which had the characteristics of mutant forms of the same strain. In 1929 Vladimir Sertic was the first to report that it was possible to obtain phages that apparently adapted to be able to grow on strains that were normally resistant to such phages. Salvador Luria made a systematic study of host range mutants in 1945 and Alfred Hershey described plaque type mutations in the same year. Phage biologists quickly adopted the obvious analogies to higher organisms and spoke of bacteriophage "strains", "races", "species", "variants", and "mutants".

As phage biologists sought to understand phage reproduction by testing for intracellular interference and competition between phages for the cellular processes involved in reproduction, they also noted that phages of differing properties but of the same strain could recombine or "cross" in the same way that higher organisms behaved. A kind of mating between strains with different genetic "markers" was developed to construct recombination frequency maps and to devise models to explain various oddities of phage biology (such as multiplicity reactivation, lysogeny, and lateral gene transfer or transduction).

The technical simplicity of phage genetics together with the statistical power of the large numbers of progeny phage and effective selection methods led to very high resolution genetic mapping experiments as well as detailed characterization of certain kinds of mutations. The ability to detect very rare recombinants meant that very close markers could be studied. In the famous T4rII gene, mutations that were in adjacent base pairs could be observed as separate markers in the mapping experiments of Seymour Benzer, thus clarifying and reconceiving the very concept of the gene. The use of mutagens with known mechanisms (insertion mutations produced by acridines) allowed Crick and Brenner to cross phage mutations in such a way as to establish, by genetic means, the triplet nature of the genetic code. With phages, the genes under study (in the phage) were separable from the environment in which they were expressed (the bacterial host), it became possible to study the rather mysterious phenomenon of suppressor mutations. Suppressors are, in general, genes that change (usually revert) other mutations but do not map in the gene of the function that was originally mutated. They are sometimes called extragenic suppressors. Bacteria that carried certain kinds of suppressor genes were used to isolate phage variants that required suppression for growth. These "sus" (suppressor sensitive, later called amber, ochre, and umber mutants for trivial reasons) mutants of phage turned out to be important in understanding the role of transfer RNA and the stop codons of the genetic code in protein synthesis.

The early observation that phage infection sometimes modified the properties of the few bacterial survivors of infection suggested that phages might be mutagens of some sort. This turned out to be true in the broad sense that they caused genetic changes, but by acting as vectors to bring in new genes rather than by direct changes to existing genes. This mode of what is now called “lateral gene transfer” turns out to be of major significance in evolution and gene flow in unicellular organisms in general. Many strains of pathogenic bacteria owe their virulence to toxin genes that are associated with temperate phages (phages that can become latent without lysing their hosts) that have carried these genes into an otherwise benign organism. Common examples include the toxin genes in cholera carried on the temperate phage CTX ϕ , and the toxin genes in the diphtheria bacteria. In addition to toxins, temperate phages can control cell adhesion, invasion, and colonization properties of the bacterial host.

For molecular biologists, the detailed genetic study of a single phage, Lambda, a temperate phage of *E. coli*, provided a trove of information on both the mechanism of lateral gene transfers (such as the mechanism of genome integration and recombination) as well as the molecular processes of gene expression and regulation. These discoveries with bacteriophage led directly to the current understanding of retrovirus biology (HIV integration and viral oncogenesis, for example) as well as the entire field of transcriptional control of gene expression.

At the time phage workers were exploring host range mutants and the strain specificity of various phages, two groups observed a rather strange sort of host-range phenomenon. A phage grown on one particular host strain sometimes could grow efficiently on that host but fail to grow well on a closely related host (measured by the “efficiency of plating” e.o.p., a theoretical e.o.p. of 1 was taken to mean, without much evidence, that every physical phage particle was infective and produced one plaque on a lawn of sensitive bacteria). While the e.o.p. on the “restrictive host” was not zero, it was often in the range of 10^{-4} . The phages that escaped this restriction, however, were now somehow adapted to grow with an e.o.p. of near 1 again on the so-called restricting host. Sometimes it grew as well on the earlier host, too. It was as if the phage somehow remembered the last host in which it grew. This phenomenon seemed like some sort of unstable mutation or adaptation to the growth requirements of the new host. This phenomenon was observed in both T4 phage by Luria and Human and in phage Lambda by Weigle and Bertani in 1952 and was termed host-induced variation (later called modification) to distinguish it from stable hereditary mutation.

Host-induced modification of phages was a rather specialized and esoteric aspect of phage biology that did not attract much attention at first. The modification involved seemed to reside in the genome of the phage, but its chemical nature and physiological significance was obscure. By the mid 1960s, however, it became clear that some chemical modifications of DNA were involved, methylation of certain bases, hydroxymethylation and glycosylation in other cases. It appeared, then, that some, but not all, bacterial hosts could modify phage DNA in ways that could be recognized by other host bacteria. How this mechanism worked, however, was unclear. In the mid 1960s, however, experiments on the fate of phage DNA upon entering the bacteria showed that the phage DNA that was restricted entered the bacterial cell but was degraded rapidly after entry.

Two lines of research soon clarified this phenomenon. First, in 1969 Herbert Boyer and Daisy Roulland-Dussoix dissected the genetics of bacteria that could modify and restrict phages, and identified a three gene system (ramABC) that controlled this process: one gene controlled modification, one gene controlled restriction, and a third gene controlled both. The interpretation was that there was one gene product each for marking and degrading the DNA, and a third gene product which directed the other two gene production to specific sequences in the phage DNA, some sort of sequence recognition system. Second, starting in 1968, numerous investigators demonstrated nucleases in various systems that showed specificity for DNA which was destined for restriction *in vivo*. These various enzymes, surprisingly ubiquitous, came to be called “restriction endonucleases” (later shortened to “restriction enzymes”). In 1970, Thomas Kelly, Jr., and Hamilton Smith found that one of these enzymes, a nuclease from *H. influenza*, cleaved DNA at a specific palindromic sequence of 6 base pairs. These nucleases, with their specificity and diversity, soon were recognized as powerful new tools for gene manipulation and formed the basis for many rapid developments in biotechnology as well as basic scientific research. From an esoteric problem in phage biology of interest to a tiny handful of researchers in the 1960s, this work led to a multibillion dollar global enterprise. For anyone who thinks that support for science can and should be predicated on prospects of future payoff, the story of phage restriction and modification is certainly a cautionary tale.

The small size of phage genomes coupled with their homogeneity and ease of preparation made them the organisms of choice for the application of nucleotide sequence studies starting in the 1960s when the hypothesis of a genetic code was being explored. Phages provided a ready source of “genes” of limited complexity compared to cellular DNAs. Except for the indirect approach in which the frequency of pairs of neighboring nucleotides were compared, the first attempts at sequence comparisons were based on the formation of stable hybrid DNA duplexes between two DNAs to be tested. Ingenious variations of this method were devised including observing DNA hybrids in the electron microscope (“heteroduplex mapping”) and later hybridizations with one strand immobilized on a solid matrix (filter hybridization and “Southern” blotting). With the discovery of the sequence-specific restriction endonucleases in the 1970s, the mapping of cleavage sites on phage and small virus genomes provided a significant advance in sequence knowledge and comparisons that became a way to characterize and manipulate phage genes and genomes. When methods were developed for complete DNA sequence analysis, phage genomes were the obvious first choices for application of these powerful new techniques, and the DNA of phage ϕ X174 became the first DNA genome to be completely sequenced in 1977 by Fred Sanger and his colleagues at Cambridge University.

Phage Biochemistry

The chemical study of bacteriophage seems much simpler than the genetic and biological work on phage, probably because phage are relatively simple entities, and the techniques needed were perfected rather later than other methods. As a consequence of their small size yet delicate composition, it was hard to isolate and prepare phage preparations that were suitable for the chemists until the availability of the ultracentrifuge in the post World War 2 period.

Early study of phages relied on rather crude preparations that were probably mostly inactive because of the harsh methods of organic chemistry were unsuitable for most complex biological materials. Modern nucleoprotein chemistry was essentially unknown before World War 2. That phages contained protein and nucleic acid was clearly shown in the 1930s by Martin Schlesinger, first in Germany and later, when he was a refugee in England. His phage preps contained amino acid polymers by chemical analysis, and nucleic acids by certain diagnostic reactions used by the histochemists (the Feulgen reaction). They were semiquantitative at best. The physical chemist, William J. Elford, working with the virologist Christopher Andrewes in England used calibrated dialysis membranes as filters to get rough estimates of the sizes of different phages.

The widespread introduction in 1949 of the model L preparative ultracentrifuge by Spinco (Specialty Instrument Company, later acquired by Beckman) the spinoff company of E.G. Pickles of the University of Virginia greatly advanced the chemical and biochemical study of phages as well as other biological materials. With the ability to sediment virus particles and separate them from other cellular material ("debris"), biochemists could analyze the whole and subviral components of specific phages. Soon it was found that there was great diversity among different phages. The DNA in phages was found to be a single polymer chain, not occurring in segments such as the chromosomes of higher cells. The DNA in some small phages was found to be a single strand of DNA in the form of a covalently closed circle (ϕ X174), and some phages even contained RNA rather than DNA (f2, MS2, R17, Q β). Cases of unusual nucleic acid components, for example hydroxymethyl cytosine and deoxyuridine were found in some phages. The finding of methylation and glycosylation of DNA in phages was crucial to understanding the important discovery of phage restriction and modification.

As the biochemists elucidated new metabolic events that occurred after infection, new phage-induced enzymes were discovered, and later shown to be encoded by phage genes (rather than phage-activated cell genes). These enzymes included new DNA polymerases, phage-specific RNA polymerases and transcription factors, polynucleotide kinase, DNA ligase, and several enzymes of nucleotide metabolism. Several of these activities were unknown as cellular functions and became useful tools in nucleic acid biochemistry.

Phage biology was central to the problem of protein biosynthesis from the early 1940s. Since phage reproduction yields a burst of new extracellular material in a rapid and synchronous fashion, it was an ideal model to study the production of new protein. Early experiments with radiolabeled substrates settled the question as to the origin of the material in the new phages: it came from precursors in the cell by *de novo* synthesis after infection, rather than from repurposing pre-existing proteins. In the case of DNA, some phages produced enzymes that degraded the host DNA and reutilized the precursor nucleotides for phage DNA synthesis. These pathways became the first such steps in the central dogma to be dissected by *in vitro* study of the replication machinery with small phage ϕ X174 DNA as the template. The discovery of phages containing RNA genomes provided an ideal source of RNA that could be used to test the new ideas about messenger RNA and ribosome function in the 1960s.

Phage and Biotechnology

The first inkling that phages might be exploited for technological applications (excluding phage for medical therapies) was the demonstration that a phage could be used to isolate and purify a cellular gene. In 1969 Jon Beckwith and his colleagues isolated pure lac operon DNA from *E. coli* using the technology afforded by Lambda phages that had incorporated that cellular DNA to become a "transducing phage". While this method was complicated and of apparent limited application, the program to isolate and purify specific genes for biotechnological applications had been launched. The subsequent discovery that restriction endonucleases could be used to prepare genes and gene fragments at will, along with the use of phages and plasmids as vectors to introduce genes into cells meant that this new technology had come of age. Phage biologists had developed a good understanding of the process of transduction (finding phages that had incorporated cell genes into their genomes) meant that phages such as Lambda were rapidly exploited as vectors for introducing a specific DNA sequence into a single host cell that could then be grown up into a mass culture from a single, genetically defined progenitor, a process that came to be called "molecular cloning" or simply cloning (derived from the original meaning from plant biology, "a shoot" or "offspring").

The understanding of gene regulation in phages, obtained from years of basic phage research, provided the new generation of biotechnologists with tools to control the expression of inserted genes at will. A particularly important technology depended on the discovery that one *E. coli* phage, T7, encoded an entirely new RNA polymerase that transcribed only certain genes expressed late in the phage infectious cycle. The transcription signals for this polymerase were linked to the genes to be cloned and thus their expression would only occur if the T7 RNA polymerase was present and active. By controlling this RNA polymerase in turn, the genetic engineer could turn the cloned gene on and off as needed. This system was particularly useful since many genes made products that were detrimental to the cell growth when fully expressed, making it hard to grow large cultures with high expression levels. The T7 system, based on rather esoteric phage research, turned out to make possible the overproduction of cloned gene products in vast excess for other biotechnological uses. In some cases, up to half of the intracellular protein could be forced from

the cloned gene, in effect, making the crude cell extract 50% pure to begin with. Much of the current progress in structural biology owes its success to these phage expression systems which produce abundant quantities of proteins normally found in miniscule amounts in the cell.

Another ingenious application of phage biology to biotechnological problems was the development of “phage display” methods, pioneered by George Smith in 1985. Since phages have multiple copies of identical coat proteins on their surface and since these coat proteins are encoded by the phage genome, it was possible to insert a mixture of foreign gene sequences into the coat protein genes of individual phages in such a way that the phages produced fusion proteins that could still function as a coat protein molecule yet at the same time “display” some of the foreign protein domains on the surface of the phage. A mixture of phages, each containing a different introduced foreign sequence attached to its coat protein gene, was called a “phage display library”. The power of this method was based on various ways of selecting for the properties of the foreign, “displayed” protein. Affinity methods with a chemical ligand or a protein target linked to a solid matrix could then be used to adsorb only those phages which “displayed” a specific functional cloned gene. Antibody affinity methods were sometimes used as well. The beauty of this method, is that an individual phage, selected by virtue of that particular phage carrying the specific selected gene, could be plaque-purified and grown into a pure stock of phage with only the desired cloned gene.

Another recent tool for genetic engineers and biotechnologists that has only a peripheral relation to the history of bacteriophage is the gene editing techniques based on the CRISPR Cas 9 system. CRISPR is an acronym for “clustered regularly interspaced short palindromic repeats”, a description of DNA sequence regularities noted in bacterial DNA sequences by several research groups between 1987 and 2000. The ubiquity of these regularities and their relation to small RNAs led researchers to seek some function for these sequences. Eventually, they were found to be related to a DNA cutting function that was connected to one of the many ways that prokaryotic cells seem to defend against lateral gene transfer, in particular, bacteriophages. The exploitation of this system for simple alteration of gene sequences represents a major advance in gene manipulation technology. It is historically incorrect, however, to present the history of CRISPR as part of the history of bacteriophages, since this mechanism was applied to phage biology only *post hoc*, and phage research had essentially no role in its discovery or elucidation, serving only as a subsequent biological justification for its presence in cells.

Phage Ecology and Evolution

Phages are ubiquitous in the biosphere, but only relatively recently has the diversity and ecological importance of bacteriophages attracted much attention. Roger Hendrix noted that, given that the average phage titer of the world’s sea waters is about 10^8 per ml., there are about 75 million blue whale units of phage on earth. That is, the combined global mass of phages equals that of the mass of about 75 million blue whales, clearly an impressive number. Placed end-to-end, these tiny phages would stretch about 100 million light years, about 100 times the diameter of our own galaxy. Why are phages so abundant? What is their function in diverse ecosystems? How many kinds of phages are there? Only recently have these questions been studied.

Early phage researchers were troubled by the differing results they obtained with phages isolated from nature. D’Herelle and his colleagues tabulated some of their isolates and noted that they differed (in no obvious or systematic way) in size, immunological properties, host range, grow rates, and so on. Later, when phages were examined under the electron microscope, diversity but no clear systematics emerged. For years, since its first report in 1971 under Peter Wildy, the International Committee on the Nomenclature of Viruses (ICNV) has struggled (with essentially no success) to systematize the classification of viruses including phages. Every year, the diversity of phages continues to surprise phage biologists, especially with more study of the archaea and their phages.

Microbes are now recognized as more than just passive parasites, rather they are essential symbionts or key components of complex ecosystems. Phages are now recognized as playing an important role in many biological communities. For example, the interplay of phages and various cyanobacteria in the oceans are crucial to the global carbon cycle. Without massive phage lysis of cyanobacteria every day, atmospheric carbon would be sequestered in these bacteria, sink to the ocean floor (eventually becoming oil) but in the meantime, the depletion of atmospheric CO_2 would reduce the greenhouse effect so much that the entire planet could freeze.

Another example of phage-host equilibrium is found in the Ganges River in India. For millennia Hindus have used this sacred river for interment of the remains of the dead. In a traditionally endemic cholera region, it is surprising that the Ganges water is not a source of major cholera infections. Over centuries, apparently, there had been an evolution of anti-cholera phages in the Ganges that effectively suppresses the cholera vibrio populations despite the episodic contaminations during lethal disease outbreaks. This “Ganges paradox” was noted long before phages were discovered, but this observation cannot be considered as an earlier “discovery” of phages.

Conclusion

Bacteriophages, discovered just over a century ago, are the most prevalent biological agents on our planet. They are also likely the most diverse. Their small size, simple genetic and physical structure, and rapid reproduction seem to account for their adaptability, their multiple ecological roles and impact, and their utility for diverse scientific purposes. Some phages were exploited from their

first discovery as anti-infectious disease agents in human and animal medicine. Others, because of their seemingly simplicity, were useful biological models that led to deep insights into basic biological problems such as heredity and cellular physiology. Knowledge of phage biology and biochemistry together with their ease of laboratory manipulation led to diverse applications in biotechnology far removed from their natural biological activities. The gradual recognition of the diversity and complexities of microbial ecology has recently brought phages once again into a central role in the global biological economy, extending even as far as having a part to play in the eventual attack on the problem of global climate change.

This is an update of B.A. Fane, M. Chen, J.E. Cherwa, A. Uchiyama, Icosahedral ssDNA Bacterial Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00456-8.

Glossary

Ångström (Å) 10^{-10} m. The unit used when describing distances within protein structures.

T = 1 icosahedron A geometric shape consisting of 20 faces and 12 vertices. A T = 1 virion is composed of 60 viral coat proteins.

π - π stacking Attractive, noncovalent interactions between aromatic rings.

Procapsid A viral assembly intermediate containing a full complement of scaffolding proteins but devoid of a genome.

Scaffolding protein A protein that directs the assembly of the virus, found in the procapsid assembly intermediate but not in the mature virion.

S value or Svedberg A unit of speed to describe the rate a particle moves through a gradient.

History

Sometime in the 1920s, Les Années Folles, Sertic and Bulgakov isolated bacteriophage ϕ X174, the most well-known virus of the *Microviridae* (micro: Greek for small). From the onset it was an *enfant-terrible*, so different from the other bacteriophages isolated during this period of extensive phage discovery. It was unusually tiny, readily passing through the smallest of ultrafilters. This biophysical characteristic defined its “race,” race X (Roman numeral ten) and the isolate was placed in a vial labeled #174, from which the phage derived its name, the race X phage (ϕ) in test tube #174. And there it sat, relatively unperturbed, for decades. The first electron micrographs revealed small, vague isometric particles, vastly different from the tailed morphologies, typically associated with bacteriophages.

The atypical capsid encapsulated an equally atypical genome, which shared qualities with both single-stranded (ss) RNA and double-stranded (ds) DNA. In 1959, Robert Sinsheimer determined that ϕ X174 genome was a single-stranded DNA molecule, the first one defined. While genetic maps of other phages consisted of orderly linear gene progressions, the ϕ X174 map was most peculiar with genes located within genes. When Sanger and colleagues sequenced the genome, the complex arrangement of overlapping reading frames was confirmed. It was so beguiling that many suspected that ϕ X174 had extraterrestrial origin. As the New York Times reported the theory, an advanced race engineered ϕ X174 and disseminated it into the cosmos where it would “persist until the evolution of intelligent life and finally of investigators interested in the genetics of phage.” Although attempts were actually made to decipher the hypothesized hidden message, they all failed. However, rumors persist that the code has been broken: it reads, “Behold this marvelous little thing.”

This small virus would continue to have a large impact on molecular biology. Arthur Kornberg and colleagues used it to elucidate the molecular mechanism of prokaryotic DNA replication. Masaki Hayashi and colleagues defined the ϕ X174 assembly pathway and were the first to demonstrate that viral DNA packaging could be achieved *in vitro*. As the genome sequence initially defied imagination in 1978, the atomic structure of the viral procapsid, the first such structure solved at this high resolution, beguiled structural virologists, with its unusual external scaffolding protein lattice. And when events were at their most bizarre, the skeletons in the family closet emerged: the gokushoviruses (Japanese for very small). These viruses escaped detection for decades, hiding within obligate intracellular parasitic bacterial hosts, Chlamydia and Bdellovibrio, or mollicutes, which are difficult to propagate in a laboratory setting. With the advent of environmental sequencing, these distant ϕ X174 relatives appear to be quite common, especially in marine environments. However, their hosts have yet to be identified.

The ϕ X174-like phages’ most distinguishing features have always been their extensive overlapping reading frames, in which new genes have been discovered as recently as 2014, and their tailless structure. Double-stranded phages use their tails to deliver their genomes. Lacking that structure, the mechanism of microvirus DNA penetration was entirely vague. In the 1970s, Jazwinski and colleagues recognized the critical involvement of protein H, a minor capsid protein, calling it the DNA pilot protein. They speculated that “protein H facilitates the transit of nucleic acid, a polyelectrolyte, through the membrane lipid bilayers, by the creation of a pore.” Thirty-five years later, their hypothesis was shown to be exceptionally insightful. In 2014, the atomic structure of the H protein’s central domain was determined. Ten H monomers form a tube that emerges from the capsid while on the host cell’s surface. Its unique biophysical features suggest energy utilization mechanisms that may be common during DNA transport through conduits.

Virion Morphology and Genome Content

All members of the *Microviridae* package circular, ssDNA genomes of positive polarity within T = 1 icosahedral capsids. High resolution atomic structures of several microvirus capsids, including ϕ X174, have been determined. The bulk of the capsid is composed of 60 copies of the coat protein (Fig. 1 and Table 1), which exhibits the common β -barrel fold, or Swiss jellyroll

Fig. 1 Virion structures. (A) A space filling rendering of the ϕ X174 virion. The major coat protein is depicted in grey. The major spike protein is depicted in blue. (B) The arrangement of five ϕ X174 coat proteins around a five-fold axis of symmetry. Numbers indicate the axis of symmetry and the number of coat proteins interacting at that axis. (C) A space filling rendering of the ϕ X174 procapsid. The major coat, major spike, and external scaffolding proteins are respectively depicted in grey, blue, and aquamarine. (D) A cryo-EM image reconstruction of gokushovirus Chp2, courtesy of S. Kailasan and M. Agbandje-McKenna.

motif, found in many icosahedral virion capsid proteins (**Fig. 1(B)**). In addition to the coat protein, ϕ X174-like viruses also contain 60 copies each of the major spike protein G and DNA binding J proteins. There are also 12 copies of a fourth structural protein, the DNA pilot protein H, which is not visible within the capsid's overall icosahedral symmetry. Although the exact location of the H proteins are not known, 10 of them form a tube that emerges from the capsid once attached to the host cell's surface.

There are several major differences between microvirus and gokushovirus capsid superstructure and protein content. In the 250 Å diameter ϕ X174-like virions (**Fig. 1(A)**), 70 Å wide spikes, composed of five G proteins, rise 30 Å above the capsid surface. By contrast, the gokushoviruses lack major spike proteins: hence, the fivefold axes of symmetry are not decorated. However, the cryoelectron microscopy image reconstruction of gokushovirus Chp2 shows mushroom-shaped protrusions at the threefold axes of symmetry. These structures, which rise approximately 55 Å above the 270 Å diameter capsid (**Fig. 1(D)**), are composed of amino acid sequences from three interacting coat proteins (VP1). The gokushovirus VP2 is also a structural protein. Although its function has not been experimentally defined, bioinformatic analysis strongly suggests it is analogous to the DNA pilot protein H. Finally, gokushoviruses likely contain another protein, VP8, which is similar to the microvirus DNA binding protein. Both are short, highly basic peptides. However, it has yet to be detected in virions. This may be due to the protein's small size and the difficulties associated with propagating large quantities of gokushoviruses for biochemical characterization.

The genetic maps of ϕ X174 and Chp2 are depicted in **Fig. 2**. Gokushoviral genomes encode neither an external scaffolding nor a major spike protein. The absence of these genes accounts for their smaller genomes. The external scaffolding protein has at least three known functions in ϕ X174 morphogenesis. It nucleates procapsid assembly, mediates the subsequent elongation reaction, and stabilizes the assembled procapsid at the two- and threefold axes of symmetry (**Fig. 1(C)**). These functions are either not required or performed by different proteins in the gokushoviruses. Gokushovirus procapsid

Table 1 Microviridae gene products

ϕ X174-like protein	Gokushovirus
	ProteinFunction
A	VP4 Stage II and Stage III DNA replication.
A*	UD ^a An unessential protein for viral propagation. It may play a role in the inhibition of host cell DNA replication and superinfection exclusion.
B	VP3 Internal scaffolding protein, required for procapsid morphogenesis and the assembly of early morphogenetic intermediates. 60 copies present in the procapsid.
C	VP5? ^b Facilitates the switch from Stage II to Stage III DNA replication. Required for Stage III DNA synthesis.
D	NP ^c External scaffolding protein, required for procapsid morphogenesis. 240 copies present in the procapsid.
E	UD Host cell lysis.
F	VP1 Major coat protein. 60 copies present in the virion and procapsid.
G	NP Major spike protein. 60 copies present in the virion and procapsid.
H	VP2? DNA pilot protein need for DNA injection, also called the minor spike protein. 12 copies in the procapsid and virion.
J	VP8? DNA binding protein, needed for DNA packaging, 60 copies present in the virion.
K	UD An unessential protein for viral propagation. It may play a role optimizing burst sizes in various hosts.

^aUD, undetermined.^bA “?” indicates a hypothesized function based on bioinformatic data.^cNP, not present in Gokushoviruses.**Fig. 2** Genetic maps. (Top) gokushovirus Chp2. (Middle) ϕ X174. (Bottom) transcripts found in ϕ X174 infected cells. The promoters and transcription terminators are indicated on the linear map of ϕ X174. Line thickness indicates relative transcript abundance. The gene A transcript is very unstable; the terminator for this transcript is unknown. For protein functions, see Table 1.

assembly is most likely mediated by the internal scaffolding protein VP3, which is analogous to the ϕ X174 internal scaffolding protein B.

In the ϕ X174-like viruses, genes A and C encode proteins mediating DNA replication. Gokushovirus gene 4 and possibly gene 5 encode their respective homologues. Lastly, gene E encodes a lysis protein. A gokushoviral equivalent has yet to be identified. All ϕ X174-like genomes contain two additional genes, A* and K. They encode proteins with unknown or poorly defined function. Furthermore, neither is required for growth under laboratory conditions. Both genes are contained within larger genes. Thus, maintaining them does not increase genome size.

The ϕ X174-like phages fall into three major clades, each one represented by a canonical virus: ϕ X174, G4 and $\alpha 3$. Genome size corresponds to the three clades: ~ 5.3 kb, ~ 5.7 kb, and ~ 6.1 kb, for the ϕ X174, G4 and $\alpha 3$ clades, respectively. Although genomes vary in size, the capsids' internal volumes are nearly identical. The $\alpha 3$ -clade genomes are more complex. They contain two versions of gene C; C_{big} and C_{small} . Both proteins are synthesized in infected cells. Although both are not required for viability, they are required for optimal fitness. In addition, three small ORFs are found in the $\alpha 3$ -clade H-A intercistronic regions, which are significantly larger than those found in the other clades. The functions of the encoded proteins, or if they are synthesized, are unknown.

Fig. 3 Surface residues and conformational changes associated with host range, attachment, and eclipse. (A) Space filling rendering of the $\alpha 3$ X-ray structure, with one G protein spike removed. The coat protein is depicted in white, the spike protein in magenta. The 6-carbon sugar binding site, which likely mediates initial attachment, is depicted in purple. Dark grey residues denote the regions within the coat protein that may merge with the lipid bilayer (see panel C). Mutations that alter host range are depicted in blue. One G protein spike has been removed to illustrate the location of these substitutions within the coat–spike protein interface. (B) The clustering of mutations affecting host range within the coat–spike interface. Proteins are depicted as described above. Mutations at blue residues alter host range. (C) Cryo-EM image reconstruction of ϕ X174 interacting with a lipid bilayer. (D and E) Interactions with the lipid bilayer at the point of cell-virus contact removes the spike protein pentamer. Before DNA ejection the coat protein pentamer is closed (panel D), whereas a pore later forms for the release of the H-tube and DNA (panel E).

Host Cell Recognition, Attachment, Eclipse and Penetration

ϕ X174-like phages recognize terminal glucose and galactose moieties on host lipopolysaccharides (LPSs). The structure of the LPS is both necessary and sufficient to mediate both attachment and penetration. In X-ray structures of ϕ X174, six coat protein residues constitute six carbon sugar binding sites when Ca^{2+} is present (Fig. 3(A)). Due to the icosahedral symmetry of the capsids, each virion has 60 such sites, which likely mediate attachment to host LPS. This is a reversible reaction: infectious virions can be dissociated from host cell surfaces.

During eclipse, also called irreversible attachment, DNA-filled virions can still be visualized on the surface of host cells. However, particles are no longer infectious when removed from membranes. A cryo-EM structures of a DNA-filled particle attached to a lipid bilayer elucidate the conformational switches associated with eclipse (Fig. 3(C, D, and E)). In this structure, the major spike pentamer at the lipid-interacting vertex has been removed, and an annulus of coat protein residues merges with the lipid bilayer, anchoring the infecting virion to the membrane. An additional conformational change was observed in a post-DNA release structure: a pore formed at the attached vertex (Fig. 3(E)). The DNA translocating conduit, or H-tube, most likely emerged through this opening during penetration (see below).

The results of host range studies underscore the importance of coat-spike protein interactions during early infection (Fig. 3(A) and (B)). Despite ~90% amino acid identity, the natural host of microvirus $\alpha 3$ is *E. coli* C; whereas microvirus ST-1 is an *E. coli* K12-specific phage. Virions attached to and eclipsed on both native and unsusceptible hosts; however, they breached only their native host's cell wall. Thus, unsusceptible host-phage interactions promote off-pathway reactions, inactivating particles without penetration. Single amino acid substitutions in either the $\alpha 3$ coat or spike proteins expand host range. The substitutions cluster around the outer circumference of the coat-spike interface (Fig. 3(A) and (B)).

During DNA penetration, bacteriophages must propel their genomes across a formidable barrier: the cell wall. The Gram-negative prokaryotic cell wall is composed of two lipid membranes that surround a peptidoglycan layer. The emblematic tail structures found

Fig. 4 The atomic structure of the ϕ X174 DNA translocating conduit, also called the H-tube. (A) Two of the ten H protein monomers are depicted in cyan. The structure is divided into two domains, which are distinguished by repeating heptad or hendecad motifs. A heptad is a group of seven, whereas a hendecad is a group of eleven. An example of each motif is highlighted in magenta. (B) Looking through the H-tube from its C-terminal opening. The inward facing amide and guanidinium containing side chains are depicted as stick models. As above, two monomers are depicted in cyan.

on double-stranded (ds) phages often perform this function. However, the ϕ X174-like phages are strictly icosahedral and lack and external tail structure. Although early studies (circa 1975) indicated that the DNA pilot protein H mediated penetration, efforts to visualize the protein within the virion structure have been dismally unsuccessful. Thus, the penetration mechanism remained unknown for almost 40 years. Then, a 13-year effort to both purify and generate diffracting H protein crystals finally yielded results.

Although protein H is a monomer in all viral assembly intermediates (see below), it crystalized as an oligomer (**Fig. 4(A)**). Ten α -helical monomers formed a 170 Å-long, coiled-coil, helical barrel. This barrel, or tube, is long enough to span membrane adhesion sites, regions of the cell wall where the inner and outer membranes make contact. Infecting particles tend to congregate at these sites. The H-tube's internal diameter is 22 Å, which can accommodate two single-stranded (ss), un-base paired DNA strands. Since the genome is circular, two ssDNA strands must simultaneously pass through the conduit. The helices run parallel to each other and a structural kink divides the tube into two domains. Domain A has a 11,3 coiled-coil structure (11 residues per 3 helical turns), whereas domain B has a 7,2 coiled-coil structure. The tube has been visualized *in situ* by cryo-EM tomography. Upon cell contact, a fully formed tube emerges from the capsid and descends into the host cell wall. After DNA delivery, the tube dissociates within the cell wall, which is necessary to preserve the cell's membrane potential.

The tube's inner surface is lined with glutamine, asparagine, and arginine amino acid side chains (**Fig. 4(B)**). Containing amide and guanidinium groups, these side chains can form hydrogen bonds with nucleic acids. The side chains point toward the tube's center and are angled towards the host cell's cytoplasm. This orientation may prevent the genome from moving backwards during transit, thus creating a one-way passage. In addition, these side chains may play two other roles during DNA transport. Although the tube's internal diameter can accommodate two ssDNA strands, it is not wide enough to accommodate the hair-pin structures formed by ss nucleic acids. By competition, these side chains, which interact with nitrogenous bases, may eliminate hair-pin structures during translocation. These tube-DNA interactions may also modulate the release of potential energy used when transporting DNA.

Mature virions; containing a highly compacted, volumetrically constrained genome; may represent the particle's highest energy state. This inherent potential energy may be used to initiate genome delivery and begin moving the genome into the host cell. In most biological systems, potential energy performs work more efficiently if released in small, usable increments. For example, during oxidative phosphorylation, for example, electrons are not directly passed from NADH_2 to O_2 . The released energy from a direct transfer would be too great for the cell to effectively harness. Instead, the electrons flow through the electron transport system, in which energy is liberated in a series of exploitable reactions. The amide and guanidinium groups may regulate genome delivery by slowing the transport process, creating a frictional force that counters the pressure driving the genome into the cell. The system can be compared to a compressed gas driven machine. In this analogy, the gas cylinder is the capsid, the packaged genome is the compressed gas, the amide and guanidinium groups are the regulatory gauge, and the H-tube is the pipe connected to the cylinder. If too much air (energy) is released at one time, the pipe could fail.

The frictional force created by the amide and guanidinium groups may prevent the transport of the entire genome, which appears to require an additional energy source. This source could be linked to DNA replication. If cells are not actively synthesizing DNA, the entire genome is not efficiently transferred. Thus, the first stage of DNA synthesis and penetration may be concurrent processes. As the ssDNA enters the cell it is converted into double-stranded molecule. The phosphate bond hydrolyzed within the deoxynucleotide triphosphate (dNTP) contains more energy than the newly formed phosphate bond in the DNA backbone. Using this small energy differential, the host cell DNA polymerase may help pull the ssDNA genome into the cell.

Due to their recent discovery, the details of gokushovirus attachment and penetration have yet to be defined. However, unlike the ϕ X174-like viruses, gokushovirus Chp2 appears to utilize a host cell protein as a receptor molecule, as opposed to LPS. The results of bioinformatic approaches combined with chlamydia phage host range studies suggest that the threefold related protrusion may govern host cell specific attachment. However, there is no direct experimental evidence to support this hypothesis.

DNA Replication

The studies of ϕ X174 DNA replication are historically significant. Positive polarity ssDNA replication strategies are complex, occurring in three separate stages, which are described below (Fig. 5). Kornberg and colleagues reconstituted the first two stages *in vitro* while Hayashi and colleagues reconstituted the third stage of DNA replication, which includes concurrent packaging of the single-stranded genome. Collectively, these studies established the first defined viral genome replication process on the biochemical level.

As single-stranded (ss) viral DNA is delivered into the infected cell via the H-tube (Fig. 5), Stage I DNA replication commences. During this stage, the ss genome is converted into a covalently closed, double-stranded (ds), circular molecule, called replicative form one (RFI) DNA. Since purified ssDNA produces progeny when transfected, host cell proteins are both necessary and sufficient for stage I replication *in vivo*. *In vitro*, a stem-loop structure in the FG intercistronic region serves as the host cell protein recognition site, which initiates the assembly of the primosome. Whether other regions of the genome can perform this function *in vivo* has yet to be determined. After primosome assembly, the complex migrates along the ssDNA in a 5'→3' direction synthesizing the requisite RNA primers for DNA replication. Addition of the holoenzyme leads to chain elongation. The 13 host cell proteins required for this stage of synthesis are the same proteins involved in replicating the host cell chromosome.

During stage II DNA synthesis, RFI DNA is amplified. In addition to the host cell proteins required for stage I replication, stage II replication is dependent on the viral A protein and the host cell rep protein, which functions as a helicase. The viral A protein binds to the stage II/III origin of replication and nicks it to initiate (+) strand synthesis, which occurs via a rolling circle mechanism. After nicking, protein A forms a covalent ester bond with the DNA, forming a relaxed circular molecule called RFII. The host cell rep protein unwinds the helix and the host ssDNA binding protein (Ssb) stabilizes the separated strands. After one round of rolling circle synthesis, protein A cuts the newly generated origin and acts as a ligase, generating a covalently closed circular molecule. Minus strand synthesis is mechanistically similar to stage I DNA synthesis.

Stage III DNA synthesis involves the concurrent synthesis and packaging of the ssDNA genome. Procapsids and viral protein C are required for this reaction along with all the proteins involved in the previous stages of replication with the exception of the Ssb. Thus, a single-stranded genome is not synthesized unless there is a procapsid to accept it. As the dsDNA is unwound at the stage II/III origin of replication, competition between Ssb and protein C for binding determines whether the dsDNA or ssDNA will be synthesized. This has been demonstrated both *in vitro* and *in vivo*. *In vitro*, excess Ssb promotes another round of stage II DNA synthesis occurs. By contrast excess protein C inhibits stage II DNA replication, and single-stranded genomes are concurrently synthesized and packaged. *In vivo*, altering the Ssb/protein C ratio by exogenously over-expressing cloned genes is detrimental to plaque formation. If the ratio increases, ssDNA synthesis is delayed. Thus, fewer mature virions are formed before programmed cell lysis. Ratio decreases result in fewer RF molecules, which is the template for both genome biosynthesis and transcription. Thus, the detrimental effects are more global.

When packaging occurs, proteins A, C, and rep form a complex on the dsDNA that docks to procapsids, presumably in a groove that spans one of the twofold axes of symmetry. Procapsid binding does not occur in the absence of protein C. Mechanistically, stage III DNA synthesis is similar to the stage II (+) rolling circle synthesis. As the new (+) strand is synthesized, the displaced strand is translocated into the procapsid. After one round of synthesis, protein A, which is covalently attached to the origin of replication, cuts the newly synthesized origin and acts as a ligase to generate a covalently closed circular molecule on the displaced strand.

Fig. 5 Morphogenesis and DNA replication of ϕ X174.

Gene Expression

Since *Microviridae* contain single-stranded genomes of positive polarity, Stage I DNA synthesis, which generates the negative strand, must occur before transcription. Unlike large bacteriophages, *Microviridae* gene expression is neither temporal nor mediated by *trans*-acting mechanisms. Thus, the timing and relative production of viral proteins is entirely dependent on *cis*-acting regulation signals: promoters, transcription terminators, mRNA stability sequences, and ribosome binding sites. In the ϕ X174-like viruses, promoters are found upstream of genes A, B, and D. Terminators are found after genes J, F, G, and H (Fig. 2). The terminators are not 100% efficient; thus, a wide variety of transcripts are produced. There is a rough correlation between gene transcript abundance and the amount of encoded protein required for the viral life cycle. For example, the virus requires more copies of protein D, the external scaffolding protein, than any other viral protein. Gene D transcripts are the most abundant in the cell. Similarly, there are more transcripts of genes F, J, and G than transcripts of gene H. The relative stoichiometry of these structural proteins are 5:5:5:1, respectively. Protein expression is also affected by mRNA stability. Each mRNA species decays with a characteristic rate. Transcripts of gene A decay very rapidly, ensuring that this non-structural protein is not over expressed. And finally, regulation can also be achieved on the translational level. Despite the gene E's location within gene D on the most abundant transcript, very few E proteins, which mediate cell lysis, are translated due to an extremely pathetic ribosome binding site.

Morphogenesis

Despite extensive searches, a dependence on host molecular chaperones, such as GroEL and GroES, has never been documented. Thus, chaperone-independence is another characteristic that distinguishes the ϕ X174-like viruses from dsDNA bacteriophages. The first virally encoded assembly intermediates are the 9S and 6S particles, respective pentamers of the major coat F and spike G proteins (Fig. 5).

Unlike most viruses that utilize a scaffolding protein to mediate morphogenesis, two scaffolding proteins orchestrate ϕ X174 assembly, temporally dividing the pathway into two discernable phases. The early phase is mediated by the internal scaffolding protein B. After or during 9S particle formation, five B proteins bind to the pentamer's underside, which becomes the capsid's internal surface. The B proteins also recruits one copy of the DNA pilot protein H. However, the DNA pilot protein is not required for assembly, as H-less particles can be assembled into uninfected, virus-like particles. The finished product is the 9S* particle. Early assembly then concludes when a major spike protein G pentamer, the 6S particle, binds to the top of the 9S* particle, forming the 12S* assembly intermediate. As previously discussed, the DNA pilot H protein forms a decameric tube for DNA delivery. However, 9S* and 12S* assembly intermediate contain one copy of the H protein. Thus, the H-tube's discovery was not expected and formation must occur after capsid assembly.

Coat-internal scaffolding protein contacts are mediated primarily by aromatic interactions, creating an elaborate π - π stacking network (Fig. 6(D)). While the X-ray structure elucidates the molecular details of the coat-scaffolding protein interactions, genetic and biochemical analyses elucidate the functional consequences. The π - π stacking network has been mutationally modified to both eliminate or alter B protein binding. The former leads to 9S particles aggregation, whereas the latter kinetically traps 9S* or 12S* assembly intermediates. Thus, the B protein temporally guides the coat protein through assembly. It suppresses interactions between coat protein pentamers until late assembly and ensures that 9S* and 12S* particles are primed to respectively associate with 6S pentamers and the external scaffolding protein D, which orchestrates late assembly. Mutations within the B protein's N-terminus, which is not part of the π - π stacking network, affect H protein incorporation.

During the second phase of assembly, 240 copies of the external scaffolding protein D, arranged as dimers, organize twelve 12S* particles into the procapsid. External scaffolding proteins are rare. The only other known external scaffolding proteins belong to parasitic satellite virus systems such as bacteriophage P4. The satellite virus encodes an external scaffolding protein that hijacks the helper virus's capsid proteins, forcing them to construct a smaller capsid, which is only suitable for the satellite virus's smaller genome. Thus, the ϕ X174-like viruses are the only non-satellite viruses known to utilize an external scaffolding protein. This protein performs many of the functions typically associated with internal scaffolding proteins in single scaffolding protein systems: it nucleates procapsid assembly, organizes procapsid assembly precursors during elongation, and stabilizes the procapsid during DNA packaging.

Unique in nature, the ϕ X174 external scaffolding protein is also biophysically unique, having the inherent ability to achieve at least six different structures. The D proteins operate as dimers. 120 D protein dimers organize twelve, 12S* particles into a procapsid. There are four D subunits (D₁, D₂, D₃ and D₄) per coat protein in the procapsid (Fig. 6(A) and (C)). They are arranged as two similar, but not identical, asymmetric dimers (D₁D₂ and D₃D₄). Each subunit makes a unique set of contacts with the underlying coat protein, the spike protein, and neighboring D protein subunits. Accordingly, the structure of each subunit is unique. The atomic structure of the assembly naïve D protein dimer has also been determined. The subunits within that dimer, D_AD_B, appear poised to achieve the four structures found in the procapsid. D_A has a structure somewhat between D₁ and D₃, while D_B has a structure midway between D₂ and D₄.

The 12S* + D protein $\rightarrow$ procapsid reaction has been analyzed both *in vitro* and *in vivo*. Capsid assembly reactions are typically divided into two phases: nucleation and elongation. Nucleation reactions, which yield a short-lived nucleation complex, are generally higher order reactions and/or require higher critical concentrations than elongation reactions. Therefore, once a reaction is nucleated, a slower process, the elongation reactions quickly go to completion. This can be regarded as an evolutionary mandate.

Fig. 6 Cryo-EM and atomic renderings of the ϕ X174 procapsid. (A) Space filling rendering of the ϕ X174 procapsid. The four structurally unique external scaffolding proteins (D₁-D₄) are depicted using the colors indicated in panel C. (B) Cryo-EM rendering of the procapsid with the removal of the external scaffolding protein. (C) The four unique D proteins, depicted in shades of blue, are associated with the coat and spike proteins, respectively colored white and periwinkle. (D) Aromatic interactions between the ϕ X174 coat and internal scaffolding protein. The internal scaffolding protein is depicted in magenta. The coat protein is depicted in two shades of blue. Dark blue residues contain aromatic side chains, whereas residues with positively charged side chains are light blue. The most extensive π - π stacking interactions; the attractive, noncovalent interactions between aromatic rings; occur between the last amino acid in protein B and three aromatic coat protein residues.

If nucleation reactions occurred more readily than elongation reactions, subunits would be divided among too many nucleation complexes. This would quickly exhaust the assembly subunit pool and result in partially formed capsids. In this regard, the 12S* + external scaffolding protein D $\rightarrow$ procapsid transition is very similar to single scaffolding protein-mediated assembly systems. However, ϕ X174 has two scaffolding proteins, which has resulted in an interesting role reversal among the reactants.

Compared to other systems, the external scaffolding protein behaves more like a viral coat protein, whereas the coat protein, a component of the 12S* particle, acts more like a scaffolding protein. Typically, viral coat proteins form aberrant assemblies in the absence of scaffolding proteins, whereas scaffolding proteins alone are relatively inert. Nucleation reactions require higher coat protein critical concentrations than scaffolding protein concentrations. During elongation, the scaffolding proteins control fidelity. By contrast, the ϕ X174 external scaffolding protein D self-associates to form large heterogeneous spherical complexes. The coat proteins in the 12S* particles do not self-associate *in vitro*, *in vivo*, or in the assembled procapsid, which is held together almost exclusively by D-D protein contacts across the two-fold axes of symmetry. Remarkably, there appears to be no associations between coat protein pentamers (**Fig. 6(B)**). Lastly, nucleation dependent a high scaffolding:coat protein ratios, and 12* particles in reaction control elongation fidelity.

Gokushovirus genomes do not encode an external scaffolding protein and their assembly pathway remains to be elucidated. A gokushovirus particle containing VP3 in addition to the structural coat and DNA pilot proteins has been isolated. Unlike virions, these particles are devoid of DNA. This particle most likely represents a gokushovirus procapsid and indicates that VP3, which is not found in virions, functions as an internal scaffolding protein.

DNA Packaging and the DNA Binding Protein

Genome biosynthesis and packaging are concurrent processes in ϕ X174. The pre-initiation complex; consisting of the host cell Rep viral A and C proteins; associates with the procapsid forming the 50S complex. As described above, the viral A protein binds the origin of replication in replicative form DNA. The results of genetic studies indicate that the pre-initiation docking site resides along a two-fold axis of symmetry. The DNA binding protein J enters the procapsid during packaging and is absolutely required for genome encapsidation. The N-termini of microvirus J proteins are extremely basic and bind the genome via simple charge-charge interactions. Once in the procapsid, the J protein's C-termini, which are very hydrophobic and aromatic, compete with the internal scaffolding protein for binding to a cleft in the viral coat protein. This competition results in the extrusion of the internal scaffolding protein during the packaging reaction.

Although the majority of the packaged genome appears to exist as a dense core, the J protein's basic amino acids, along with a small cluster of basic capsid residues, tether the genome to the capsid's inner surface. In the ϕ X174 X-ray structure, the J protein forms an S shaped polypeptide chain devoid of secondary structure. The C-terminus is tightly associated with the cleft located near the center of the coat protein. Each of the 60 J proteins traces a path toward the five-fold axis of symmetry, crosses over to the adjacent capsid protein, and veers toward the C-terminus of the adjacent J protein. Thus, the DNA binding protein guides the incoming genome into a somewhat icosahedrally ordered conformation and a portion of the genome is ordered in the X-ray structure.

The biophysical characterization of ϕ X174 particles packaged with foreign genome-length DNA or mutant DNA binding proteins suggests that protein-DNA interactions influence the final stages of morphogenesis. Morphogenesis terminates with the provision to virion transition: the dissociation of the external scaffolding protein and an 8.5 Å radial collapse of the capsid pentamers around the genome. The tethered genome constrains the spatial orientation and secondary structure of the remaining nucleotides. Therefore, altering the tether or the base composition of the packaged nucleic acid may affect the magnitude or integrity of the collapse. However, the role of DNA-capsid interactions in ϕ X174 is not as dramatic as those seen in other viral systems in which abrogating genome-capsid interactions leads to severely aberrant particles.

Lysis

Unlike large ds bacteriophages, ssDNA microviruses do not have the genetic capacity to encode a two-component holin-endolysin system. Instead, they have evolved a small protein, lysis protein E, that inhibits peptidoglycan biosynthesis. Thus, lysis is dependent on host cell division, during which the cell becomes sensitive to osmotic pressure. The results of several elegant genetic studies elucidated protein E function. By selecting for lysis resistant cells, Ryland Young and colleagues first uncovered the *slyD* (sensitivity to lysis) gene, which encodes a peptidyl-prolyl cis-transferase-isomerase, or PPIase. However, it is unlikely that the *slyD* gene product is the E protein target. Considering the function of PPIase's in protein folding and the E protein's five prolyl bonds, it seemed more likely that the E protein was a substrate for the host cell enzyme. In fact, gene E mutants, *Epos* (plates on *slyD*), can be readily isolated. In order to determine the target of protein E, *Epos* proteins were used in a second round of selection with *slyD* cells. The surviving colonies contained mutations in the *mraY* gene, which encodes translocase I. This enzyme catalyzes the formation of the first lipid-linked intermediate in cell wall biosynthesis. In the presence of protein E, its activity is greatly reduced. Thus, it is likely the E protein's direct target.

Evolution and Evolutionary Studies

The evolutionary relationship between the gokushoviruses and the ϕ X174-like viruses remains somewhat obscure. There is a deep evolutionary rift between the two groups, with no known intermediate species. The rift is likely a function of their host's biology and not the hosts' evolutionary relationship. The gokushoviruses have been isolated from obligated intracellular parasitic bacteria and mollicutes. For example, the *Bdellovibrio* host for the gokushovirus ϕ MH2K is a proteobacterium, like the ϕ X174-like phage hosts, but ϕ MH2K is much more closely related to the phages of chlamydia, which is in an unrelated bacterial phylum. Two of the primary differences between the two groups are the external scaffolding and spike proteins.

Many gokusho or gokusho-like viral genomes have been detected in environmental samples, primarily oceanic, and microbiomes. However, their hosts have yet to be identified. Nonetheless, these viruses likely play a major role in the shape and functioning of ecosystems.

Evolution of a Two Scaffolding Protein System

While the existence of two scaffolding proteins is unique in any system, it is particularly peculiar for T = 1 capsids. No other T = 1 virus requires a scaffolding protein, let alone two. The results of an exhaustive search for new *E. coli* ϕ X174-like phages indicate that the 47 known species can be divided into three separate clades, typified by bacteriophages ϕ X174, G4 and α 3. Although there is evidence for some horizontal gene transfer between the species, the extent is considerably lower than that observed for dsDNA

viruses. The one gene that seems to be the most recent acquisition, or at least its present form, is the external scaffolding protein gene, which appears to have originated in the ϕ X174 clade and spread to the two the others.

An accumulation of both genetic, biochemical, and structural data indicates that the external scaffolding protein is more essential for morphogenesis. The internal scaffolding protein, on the other hand, may be best viewed as an efficiency protein, facilitating several morphogenetic reactions, but not absolutely essential for any one in particular. This hypothesis was tested by evolving a sextuple mutant strain that no longer requires the internal scaffolding protein. Although mutations in structural and external scaffolding proteins did arise, two mutations were found in promoters upstream of the external scaffolding gene, leading to its over-expression. These two regulatory mutations, along with one conferring a substitution in the external scaffolding protein, have a kinetic effect on virion assembly. This indicates that one function of the internal scaffolding protein is to lower the critical concentration of the external scaffolding protein needed to nucleate procapsid assembly.

The morphogenesis of wild-type ϕ X174 is extremely rapid, progeny virions can be detected as quickly as 5.0 min post infection, which may be critical for a small phage without the genome content to encode super infection exclusion functions. At five minutes post infection, most other phages are just concluding early gene expression. Rapid morphogenesis may be a consequence of having two scaffolding proteins, allowing the ϕ X174-like viruses to compete with the larger and vastly more prevalent dsDNA phages. In this evolutionary model, the external scaffolding protein is a recent acquisition. Those phages that did not acquire the gene, the gokushoviruses, may have persisted by finding a niche free of competition: obligate intracellular parasitic hosts like chlamydia.

ϕ X174-Like Viruses as a Model System for Experimental Evolution

Due to the small genomes and the ability to interpret amino acid substitutions within the context of the virion and procapsid atomic structures, the ϕ X174-like viruses have become one of the leading systems for molecular evolution analyses. In studies pioneered by Jim Bull, Holly Wichman and colleagues, viruses are placed under selective conditions, and grown for numerous generations either in chemostats or by passaging viruses between fresh cell cultures. Individual genomes are sequenced at various time intervals, which monitors the appearance and disappearance of mutations. The obtained mutations differ depending on the selective conditions. While these studies identify beneficial changes in both structural and nonstructural proteins, many mutations are in genetic regulatory sequences, which most likely optimize the relative level of viral proteins synthesized under the experimental conditions.

This is an update of P.G. Stockley, Icosahedral ssRNA Bacterial Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00760-3.

Glossary

Pfu Stands for plaque-forming unit; that is the number of phage particles per host cell required to generate productive infections. Theoretically this value could be 1 but very few of the phage that attach to the edge of a pilus will get access to the inside of a cell, so Pfu values in the 100s are not uncommon.

Polycistronic RNA The term cistron was coined to mean any section of an mRNA that gets translated. The RNA phage genomes are “polycistronic” because they encode multiple protein products.

Quasi-equivalent conformers These are different conformations of the identical polypeptide sequence that form at the differing symmetry-related positions of viral capsids.

Translational repression Refers to the process whereby a protein product interacts at a defined site within a mRNA molecule preventing translation of the downstream cistron.

Triangulation number, T Is defined mathematically as $T = (h^2 + hk + k^2)$, where h and k are any pair of positive integers, including zero. For instance giving rise to triangulation numbers of 1 for h, k = 1,0, and 3 for h, k = 1,1. These h and k values can be determined by analysis of real viruses by analyzing them in terms of networks of equilateral triangles that cover the surface of a sphere. The details of this analysis can be found in the article by Caspar and Klug listed under further reading.

UTR Untranslated region, found at the 5' and 3' ends of phage RNA genome where they form specific secondary structures recognized by the replication enzyme.

Icosahedral ssRNA Bacterial Viruses

Background

Some *E. coli* cells contain a separate genetic element, the F factor plasmid, in addition to their chromosomal DNA. Such F+ bacteria produce a pilus protein that self-assembles a hair-like appendage, the pilus, on the outside of the cell that is an essential part of conjunctive DNA transfer between bacterial cells. This primitive version of sexual genetic transfer is known as conjugation and the term “male” is used for bacteria carrying the F factor. A group of bacterial viruses, the RNA phages exploit this feature binding to the sides of the pilus and transferring their ssRNA genomes into the bacterium as the pilus retracts, the latter being part of its natural function. Tim Loeb working in Norton Zinder's laboratory at the Rockefeller University in New York was the first to realize that there might be such male-specific bacterial viruses, bacteriophages. Together they isolated and began to characterise such phages from an initial sample of raw sewage. One intensively studied version known as MS2 is believed to have been named because it was male-specific factor 2, although there are unconfirmed stories that the MS also stands for Metropolitan Sewer, the source of some of the samples they screened for phage!

Similar phages, all now grouped as *Leviviruses*, were rapidly isolated world-wide after this initial discovery and we now know that such phages are extremely common in the environment with up to 10^7 Pfu/mL in sewage. Both human and animal hosts appear to harbor *E. coli* populations able to support such phages which are thus termed coliphage. Virtually identical phages have been found that are specific to *Acinetobacter* (AP205) and other gram-negative bacteria. In such phages the infection process still occurs via pili but these are distinct from the sex pili of *E. coli*. Phage PRR1, for instance, infects hosts via pili encoded by incompatibility type P plasmids which are widely dispersed allowing the phage to infect a range of different bacterial cells. On the basis of immunological cross-reactivity and genome organization the *Leviviridae* are classified into two genera. These have been further sub-divided into two groups. All the phages are members of the *Leviviridae* or the *Alleloleviridae*, the latter being distinguished by having slightly longer genomes and because of the presence of read-through products from the CP gene (Fig. 1). Sub-groups I and II are typified by phages MS2 and GA, respectively, whilst typical Group III and IV phages are Q β and SP, respectively.

They have a single copy, positive-sense, single-stranded genomic RNA (gRNA) of ~3–4.5 kb in length, that encodes a maturation protein (MP, also called A or A2, depending on the phage), a coat protein subunit (CP), a replicase subunit and a lysis protein (Fig. 1). The two most studied are canonical genetic systems specific for the *E. coli* F pilus: MS2, the first organism to have its genome sequenced, and Q β , which provided the genome and replicase for the early studies of RNA-dependent RNA replication and in vitro evolution. Until recently only ~30 *Leviviridae* genomes had been deposited in the NCBI database, more than half of which are F-specific phages resembling MS2 or Q β in genome organization. However, orders of magnitude more novel ssRNA phages have been identified in meta-transcriptomes, which may infect more diverse groups of hosts and represent a vast “dark matter” that is under-characterized.

Fig. 1 Genetic maps and structural organization of ssRNA phages. (A) Color-coded genomic maps of the ssRNA phages Q β , AP205, MS2, PP7, ϕ Cb5, M, from top to bottom. The gene for the lysis protein (black) is the most variable among different ssRNA phages. Note that for Q β , the lysis protein also acts as the maturation protein; and it has an additional minor coat protein due to the read-through of the gene for the major coat protein (Read-through: green). (B) Cross-sectional view of an ssRNA phage. The front part of the capsid has been removed to show the interior of the virion and the various components are labeled. (C) Shows an electron micrograph of an *E. coli* cell with two pili, each of which is decorated with MS2 phage, i.e., the initial complex with the host receptor, see inset for details. The magnification is $\sim 16,000\times$ and reveals the relative sizes of the host and its virus particles. Pili occasionally contract toward their host and it is believed that during this process the bound phage get internalized but for MS2 only the MP-RNA complex gets into the cell. Once there a protease cleaves the MP allowing the RNA to act as an mRNA for production of phage proteins. (D) Life-cycle post genome entry including translation to produce phage proteins, genomic RNA replication, self-assembly of progeny phage particles and subsequent lysis of the host. Reproduced from Paranchych, W., 1975. Attachment, ejection and penetration stages of the RNA phage infectious process. In: Zinder, N.D. (Ed.), RNA Phages. Watson, J.D., Hopkins, N.H., Roberts, J.W., Steltz, J.A., Winer, A.M., 1993. Molecular Biology of the Gene : General Principle, vol. I. fifth ed. New Delhi: Pearson Education, Inc., with permission.

Phage lifecycle

Infectious phage must contain at least one copy of the MP as well as a CP shell to protect the genome (Fig. 1). Infection is initiated by the interaction of MP with the edge of a bacterial pilus (Fig. 1C), the first observation that this component is both structural and at least partially exposed to the surface. Loss of MP results in particles that are no longer infectious and renders part of the

Fig. 2 The Regulation of Phage Gene Expression. (A) The amounts of each of the encoded proteins produced during an infection cycle. Although each gene is present in equal amounts along each copy of every genome there is a dramatic difference in the amounts of each protein in the cell, reflecting the requirements for different numbers of these protein products for replication, self-assembly of progeny phage and lysis of the host. The implication is that the expression of these protein products is tightly controlled. Editor: use images from the 3rd edition (B) RNA-RNA and Translational Repression - At times in the phage lifecycle the stem-loop structures (right) encompassing the start codon for the phage encoded replicase subunit are sequestered by long range Watson-Crick base-pairing interactions to a segment of the CP gene, the Min Jou sequence (left). Translation of the CP gene releases this sequence allowing the expression of replicase. However, as the CP concentration rises it binds sequence-specifically to a cognate stem-loop sequestering the replicase start codon leading to translational repression. Editor: use images from the 3rd edition. Reproduced from Van Duin, J., 1988. Single-stranded RNA bacteriophages. In: Calendar, R., (Ed.), *The Bacteriophages*, vol. 1. New York & London: Plenum Press, pp. 117–167 with permission.

genome RNase accessible, implying a second function namely MP-RNA interaction. Careful work by Paranchych and others shows that infection occurs when just the MP-gRNA complex enters the cell, the CP subunits of the capsid being left outside. The precise mechanism of how the MP-RNA complex is internalized has not been worked out in any detail. Once inside however the MP undergoes a single proteolytic cleavage event which initiates the phage lifecycle in the cell (Fig. 1(D)).

Expression of phage proteins is tightly controlled, both in the amounts and timing of the appearance of each protein product, reflecting the need for differing amounts of phage proteins, despite their genes all being present equally on the same RNA (Fig. 2). An essential early gene product is the RNA-dependent RNA polymerase. This contains only one phage-encoded subunit, from the 3' replicase gene, which forms an active complex with host proteins S1 and elongation factors Tu and Ts. This enzyme then copies the entire positive-sense strand into its negative-sense complement, and then repeats the process on the negative-strand to create progeny genomes. The complementary strands are only base-paired in the region being copied preventing formation of dsRNA. These events require the enzyme to recognize distinct signals in the 3' UTRs of each strand. The positive-sense progeny produced serve as mRNAs for the production of phage proteins and subsequently get repurposed as assembly substrates during the formation of progeny phage. The replication enzyme from Q β was used to establish *in vitro* RNA transcription. Subsequent evolution studies identified a non-viral replicator that outcompeted the genome as a replication substrate revealing the compromises required to encompass the multiple functions needed to create an infectious particle.

CP expression occurs from the start of infection and its level increases throughout an infection, reflecting the need to assemble large numbers (> 1000) progeny phage. There seems little regulation of this expression other than the sequence and stability of the initiator hairpin structure that binds the ribosome. Upstream flanking sequences may also positively promote translation, perhaps by forming structures that favor binding of the ribosome to this site. The phage makes more MP than is strictly necessary but its level is tightly controlled. In part this regulation is due to poor translational initiation, the start codon in MS2 being GUG not AUG. Additionally, the ribosome binding site of the MP gene may base pair with an internal region of its gene preventing translation. This creates a window for expression in which as the RNA is replicated the MP start site is free to bind ribosomes but these must compete with internal base-pairing once the full MP gene sequence is present.

The replicase is made at a level of ~ 5 copies/genome and its levels are also tightly controlled. This regulation is achieved in two distinct ways. As with the MP gene the ribosome replicase start site can be sequestered in another long-range base pairing interaction, this time with a section of the CP gene. Translation of the CP gene sequesters this complementary sequence, known as the Min Jou sequence after its discoverer, freeing the region around the start of the replicase gene so that it can fold to form a ribosome binding site (Fig. 2(B)).

However replicase expression is further controlled via a translational repression complex that forms with the phage CP. A stem-loop translational operator hairpin, TR (Fig. 2(B)) can form that is bound sequence-specifically by a CP dimer in a concentration-dependent fashion. This operator encompasses the start codon for replicase and formation of this complex effectively switches off replicase translation. The complex has become a paradigm for studies of sequence-specific RNA-protein recognition. It also appears to be the site of assembly initiation of the phage CP shell around the genome (see below). Regulating phage gene expression is vital because of the importance of timing the switch in the viral life-cycle from replication to assembly of progeny phage. During that process the viral mRNAs are repurposed as assembly substrates.

Lysis – cell death – is the ultimate result of the infection ensuring release of progeny phage. In MS2, this is achieved by the action of a phage-encoded lysis protein expressed inefficiently from the +1 reading-frame within the CP gene (Fig. 1). The lysis

Fig. 3 Structure & Assembly of RNA Phages. (A) Asymmetric cryo-EM reconstructions of MS2 and Q β shown with the front half of their CP shells removed to reveal the density for the genome (light blue) and the MP (purple). The encapsidated CP dimer in Q β is shown in green. (B) CP quasi-conformations required to assemble the $T = 3$ capsids. CP dimers are either symmetric (C/C conformation) or asymmetric (A/B conformations). These different conformers interdigitate at particle 3-fold vertices (Δ), but 5-folds ($\blacklozenge$) are surrounded only by B-type conformers. (C) Proposed model for assembly. Multiple TR-like stem-loops across the MS2 genome (red cylinders) trigger CP dimer conformational change in favor of the A/B conformer. Multiple such cognate RNA-CP interactions collectively make assembly highly efficient, initially collapsing the CP-free RNA conformation and promoting the assembly pathway illustrated.

protein is the last gene product to begin expression, consistent with its functional role in the life-cycle. The delayed production of this gene product appears again to be a consequence of translational control, the ribosome binding site allowing initiation of translation being inaccessible until the ribosome translating the CP gene terminates at a defined site. Experiments where the CP gene stop codons are moved further 3' prevent lysis expression implying that correctly regulated expression is due to a defined RNA folding event similar to those controlling replicase translational repression. Variations of the details of this mechanism may partially account for the frequency of read-through products in some of the CPs in some phages.

Phage Structure and Assembly

Simple spherical viruses like the RNA phages were important at the beginning of the study of molecular biology since they posed the important question of how a gene product could encapsidate the RNA that encoded it. The solution of course is that the RNA genome is used multiple times as an mRNA producing many small CP subunits that subsequently associate to form a closed container into which the nucleic acid co-assembled. The simplest form of such a container would be highly symmetrical, allowing each CP to make identical intermolecular contacts with its neighbors. The container with the highest symmetry is an icosahedron, implying that viral shells should contain 60 CP subunits. Caspar & Klug extended this idea to include higher CP stoichiometries that are multiples of 60 arguing that CPs can occupy quasi-equivalent symmetry-related positions in the capsid. This concept has been central to virology for over 50 years. It solves the problem of how viruses can encode a container large enough for their genetic material. Very many simple viral capsids correspond to this arrangement in which icosahedral facets are sub-triangulated by multiple CP subunits, whose numbers and arrangements can be predicted to derive a Triangulation Number (see Glossary) for a viral particle.

The earliest viral structures, starting with Harrison's pioneering structure of the $T = 3$ Tomato Bushy Stunt Virus, seemed to confirm this concept. They used symmetry-averaging to calculate atomic resolution electron density maps. However, whilst such structures produce high resolution maps of viral CP shells major non-symmetrical components such as the viral genome and any minor structural proteins are not seen. Indeed flexible sections of the CPs, which are often involved in contacts to the genome, are also lost. This anomaly is being addressed by using modern cryo-electron microscopy (cryo-EM) which unlike crystallography can calculate atomic resolution reconstructions of virions without symmetry averaging, resulting in electron density maps that reveal the previously unseen asymmetric components.

Asymmetric cryo-EM structures at close to atomic resolution are now available for both MS2 and Q β (Fig. 3). They reveal shells of CP dimers that roughly occupy the lattice positions expected for the A/B and C/C dimers needed to create an idealized $T = 3$ particle (see above). However, this lattice is interrupted by the presence of a single copy of the MP, which replaces a CP dimer at a C/C position. Also visible is $\sim 80\%$ of the electron density for the encapsidated genomes. Instead of an esthetically pleasing icosahedrally-symmetric protein shell of CPs we can now see the viral molecular machinery poised for host attachment and infection.

Given that the encapsidated genome appears well-ordered a reasonable assumption is that it consists of only a single conformer. Protein-free RNA molecules of that size (3569 nt for MS2) would be expected to sample multiple conformational states in an ensemble of structures. Thus the structures of these particles begs an important question of how such a quasi-symmetrical structure can be assembled around a highly asymmetric genome, incorporating the MP as it occurs. This problem has been

addressed using a variety of biophysical techniques. Mass spectrometry and NMR spectroscopy showed that TR operator-CP dimer interaction biases the conformational preference of the CP dimer towards the A/B state. The sequence-specifically bound RNA acts as an allosteric effector for this change. Sixty A/B dimers are required to make the $T = 3$ capsid of the virion but there is only one copy of the TR sequence within the genome. Single molecule fluorescence measurements of the hydrodynamic radius of dye-labeled genomes in assembly reactions, however, have revealed that the RNA must be compacted during encapsidation. This compaction is driven by multiple CP dimers binding to sites across the genome, consistent with experiments triggering assembly *in vitro* with stem-loops other than TR. The multiple genomic sites being bound have been termed Packaging Signals (PSs), and assembly using such sites is PS-mediated assembly. They act to make the assembly process highly efficient in the biological environment restricting the molecular components from exploring all possible assembly pathways.

The asymmetric structure of MS2 confirms these predictions about its assembly mechanism. There are > 50 stem-loops that point at CP dimers and could act as PSs, and 15 of these remain bound by their CP partners in the virion. Not all the PS sites need to stay bound following assembly, since they are only required to act as allosteric effectors during the assembly process itself. Whilst this mechanism accounts for assembly of a symmetric $T = 3$ particle it does not explain how the unique MP gets incorporated, creating the biologically functional asymmetric protein shell. Cryo-EM and earlier biochemistry reveal that MP makes a specific genome contact in an additional stem-loop adjacent to the 3' end of the genome. This may occur before or shortly after translational repression of the replicase cistron by binding of a CP dimer at TR (see above). A fascinating insight into the assembly mechanism, and potentially virion evolution, comes from the fact that in the infectious phage particle the CP dimer at TR, which includes the start codon of the replicase is in contact with the MP bound to the untranslated region at the end of that gene. Thus both structural proteins act to sequester the replicase gene, preventing the gene from being translated and any existing replicase beginning to make the minus-strand. The importance of this arrangement is highlighted by a variation seen in the structure of Q β , where instead of replacing a CP dimer it appears that the MP protein may have forced the CP dimer to become internalized within the phage protein shell.

Biotechnological Applications

RNA phage biology has been exploited in many differing areas of biotechnology. The sequence-specific interaction between the phage CP dimer and its RNA translational operator has been used to monitor RNA-protein interactions and RNA/RNA-binding protein localization in cells using fluorescently modified components/antibodies. In addition the ease by which virus-like particles can be assembled has led to their use to create bespoke VLPs carrying artificial cargoes, such as toxins or siRNAs that can then be used therapeutically. Bacteriophage MS2 CP has become the first viral protein to have every one of its natural amino acids mutated creating a detailed structure-function map. It is therefore very likely that this list of applications of this system will continue to expand.

Nomenclature

ATP Adenosine triphosphate
Cryo-EM Cryo electron microscopy
Da Dalton, 1.67×10^{-24} g
dsRNA Double stranded RNA
LPS Lipopolysaccharide
mRNA Messenger RNA
NC Nucleocapsid
NMR Nuclear magnetic resonance
NTP Nucleoside triphosphate
NTPase Nucleoside tri-phosphatase

OM Outer membrane
PC Procapsid
RdRP RNA-dependent RNA polymerase
RLPS Rough lipopolysaccharide
S_{20,w} Sedimentation coefficient, standardized to conditions corresponding to pure water at 20°C and extrapolated to zero protein concentration, 10^{-13} s, and it's expressed in Svedberg value S
ssRNA Single stranded RNA
T Triangulation number

Glossary

Capsid The protein shell of the virus containing the nucleic acid genome.
Carrier state The complete or incomplete viral genome maintained in the host cell as a stable episome without cell lysis.
Genomic precursor Viral mRNA that is subsequently packaged in the capsid.
Genomic segment One of the 3 double stranded RNA molecules in the virus core.
Nucleocapsid Expanded, RNA filled capsid, covered by the outer shell matrix and capable of transcription.
Packaging Insertion of the mRNA genome precursors into the virus core

Polymerase complex The viral protein complex that contains the RNA polymerase and the dsRNA genome segments. The structure is capable of replication and transcription of the viral genome.
Procapsid The viral capsid prior to acquisition of the genome precursors.
Reverse genetics Rescue of an RNA virus genome from cDNA recombinant clones.
Self-assembly Mechanism with which protein precursors organize into a defined structure utilizing local interactions and without the intervention of external direction.

Introduction

The *Cystoviridae* Family

The cystoviruses (family *Cystoviridae*) are a unique group of viruses that have proven of great utility in the study of many facets of molecular virology. First discovered in 1973 as a bacteriophage of phytopathogenic pseudomonads, $\phi 6$ proved unique in that it contained lipid and possessed a genome consisting of three strands of double-stranded RNA (dsRNA). The replicative mechanism and structure make cystoviruses analogous to members of the *Reoviridae* family, therefore much of the research interest was driven to shed light on analogous systems in the pathological reoviruses. Until 1999, $\phi 6$ had been the only member identified in the genus and the extensive investigation of its genomic sequence, replication cycle, structure, and RNA packaging system formed the foundation of this field. Additional viruses have since been isolated that share the physical and structural characteristics of $\phi 6$. All are chloroform-sensitive, indicating they contain lipids, derived from the host cell. Their genome consists of three dsRNA segments of different sizes denoted 'S', 'M' and 'L' for 'small', 'medium', and 'large', respectively. (Transcripts from the three genome segments are designated in lower case; *i.e.*, 's', 'm', and 'l', respectively). The overall viral organization is shown schematically in Fig. 1. All the cystoviruses are virulent and infect strains of the plant pathogen, *Pseudomonas phaseolicola*. Based on genetic sequence and host range analysis, the well-classified cystovirus bacteriophages were divided into two major groups in which $\phi 7$, $\phi 9$, $\phi 10$, and $\phi 11$ are closely related to $\phi 6$, while $\phi 8$, $\phi 12$, and $\phi 13$ are distantly related to $\phi 6$. Additional cystovirus family members have subsequently been isolated from environmental samples throughout the United States, Finland and China indicating the genus is extremely widespread. After the synthesis and isolation of a recombinant $\phi 6$ procapsid (PC) in 1990, seminal studies of the structure, replication, genome packaging, and transcriptional regulation of $\phi 6$ were performed. This research established the first *in vitro* RNA packaging and replication assay for this class of viruses and subsequently utilized it to rescue infectious particles.

Fig. 1 Schematic organization of layered structure of the $\phi 6$ virion. The inner layer, procapsid PC, includes the shell, composed of 120 copies of P1 protein or 60 non-symmetrical dimers of P1. Inside the shell, are the P2 and P7 proteins, which are localized at the 5-fold axis of symmetry portal and three ds-RNA segments, which have low symmetry quasi-concentric shell organization. The P4 proteins form a hexameric ring around the 5-fold axis; the NC includes the PC and protein P8 matrix layer, and the complete virion has envelope from the cellular bi-lipid membrane with randomly distributed P3, P6, P9, P10 and P11 proteins.

Classification and Host Range

$\phi 6$ was originally isolated from a bean straw plant that was infested with *Pseudomonas syringae* pv. *Phaseolicola*, strain HB10Y and until 1999 was the lone type in the family *Cystoviridae*. The isolation of eight additional lipid-containing, three-segmented dsRNA bacteriophages expanded the group with additional types some of which were closely related and others distantly related to $\phi 6$. The host range of cystoviruses is governed by the structure of the attachment apparatus and which cell surface receptor it utilizes. Of the $\phi 6$ and its close relatives, host infection requires binding to type IV pili. Therefore the $\phi 6$ group has a host range limited to *Pseudomonas syringae* (and for several laboratory selected $\phi 6$ mutants *Pseudomonas pseudoalcaligenes*). In species $\phi 8$, $\phi 12$, and $\phi 13$, the attachment apparatus is a heteromeric protein assembly that utilizes the rough lipopolysaccharide (RLPS) as a receptor. These types also have the ability to infect other gram-negative bacteria containing an RLPS – although without plaque formation.

In 2010 the *Cystoviridae* family was again expanded with the isolation of $\phi 2954$ from radish leaves. The base sequences for many of the genes and for the segment termini were similar but not identical to those of bacteriophage $\phi 12$. However, the host specificity was for the type IV pili of *Pseudomonas syringae* HB10Y rather than for the RLPS to which $\phi 12$ attaches. Next ϕNN was isolated from a freshwater habitat demonstrating that the virus group is quite diverse and widely distributed. This phage utilizes the type IV pilus of *Pseudomonas syringae* for attachment and phylogenetic trees of the genome segments indicate a close relationship to $\phi 6$. Of great interest was the 2016 isolation in China of ϕYY from hospital sewage, a cystovirus that uses the opportunistic pathogen *Pseudomonas aeruginosa* strain, PAO38, as a host.

Virion Structure and Properties

Physico-Chemical Properties

The virus particle molecular weight is approximately 9.9×10^7 Da, sedimentation coefficient $S_{20,w}$ approximately 405S (or 4.05×10^{-11} s) and density 1.24 g cm^{-3} in sucrose. The molecular weight of the nucleocapsid (NC) is approximately 4.0×10^7 Da. The composition is 70% (w/w) protein, 14% dsRNA, and 16% phospholipids.

Architecture of the Polymerase Complex and the Nucleocapsid

All the cystovirus members are enveloped bacteriophages of multilayered structure (Fig. 1). The first species isolated, $\phi 6$, is the best characterized in regard to its structure and assembly mechanisms. The inner layer, the PC, is composed of 60 asymmetric dimers of protein P1 that form a dodecahedral $T = 1$ (triangulation number) shell. At each of the twelve dodecahedron faces protein P4 hexamers (the packaging nucleoside triphosphatase, NTPase) localized at the 5-fold axis, protrude from the PC. The P2 and P7 proteins localized at the portal at the 5-fold axis of symmetry are within the P1 shell. The $\phi 6$ NC outer shell has icosahedral symmetry and is formed of 200 P8 trimers, a small membrane-associated protein, in a $T = 13$ matrix that partially covers the PC. The NC is enveloped by a lipid membrane with the lipids derived from the host cell cytoplasmic membrane and the viral envelope surface proteins which have an asymmetric distribution. The individual species of the cystoviruses are not entirely isomorphic but similar in overall design. The NC structures have similarity in P1, P2, P4 and, P7 organization but the P8 layer is quite different among the species. In $\phi 8$ the NC cover is virtually non-existent consisting of only 60 copies of P8, a small membrane associated protein. In contrast to $\phi 6$ and $\phi 8$, NC architecture based on analysis of cryo-electron microscope single particle reconstruction analysis placed $\phi 12$ in an intermediate category showing an incomplete $T = 13$, the P8 organization with significant vacancies occupied by protein P7 dimers.

Fig. 2 The cystovirus PC 3D structure before (unexpanded) RNA packaging and after (expanded) RNA packaging, replication and the structure of the mature NC. Data reproduced from Huiskonen, J.T., de Haas, F., Bubeck, D., *et al.*, 2006. Structure of the bacteriophage $\phi 6$ nucleocapsid suggests a mechanism for sequential RNA packaging. Structure 14, 1039–1048.

Cystoviruses package their plus sense messenger RNA (mRNA) sequentially into a preformed PC in the order s, m and l and the PC expands to accommodate the genome (Fig. 2). In $\phi 6$, packaging relies upon signals at the RNA 5' end called "pac" containing about 200 nucleotides (with extensive secondary structure) while specific sequences at the 3' end are RNA replication signals. The PC expansion is facilitated by hinge like movement of the P1 subunits approximately parallel to the two fold edges of the dodecahedral PC. The expansion and packaging activates the P2 RNA-dependent RNA polymerase (RdRP) which replicates the mRNA to dsRNA. The expanded genome-filled PC is finally enclosed within the 200 P8 trimer matrix completing the assembly of the mature NC. The packaged dsRNA genome segments appear to be located in lower symmetry quasi-concentric shells based upon electron cryo-microscopy reconstructions.

The Protein Components of the Cystovirus Portal Complex and Nucleocapsid

The cystovirus RNA portal complexes, consisting of protein elements P2, P4, and P7, are located on each of the apex of the assembled PC. There is a potential total of twelve RNA portal complexes upon the dodecahedral PC however not all the sites are occupied. The dynamic interaction of these three portal proteins governs the packaging, replication, and transcription of the viral RNA genome. This intricate molecular machine can be described in regard to each of the separate proteins and below is reviewed what is currently understood about each individual component.

P1

The PC organizing protein is P1 and it forms the framework of the entire complex. P1 interacts with the other the three portal proteins to properly position them within PC structure. The PC is built from 120 identical P1 proteins organized into a $T = 1$ shell containing 60 non-symmetric dimers where each dimer is composed of subunits A and B of the same 3-dimensional fold. The P1 crystal structure has been determined for viruses $\phi 6$ and $\phi 8$ and is a trapezoidal shape that accommodates the significant conformational changes that occur during RNA packaging (Fig. 3(A)). Intriguingly different conclusions describing the evolutionary history of the $\phi 6$ and $\phi 8$ P1's were reached by the respective research groups. The $\phi 6$ P1 was reported to show no P1 fold similarity with the known folds noted in other dsRNA viruses. Therefore the $\phi 6$ P1 structure analysis led to the suggestion that cystoviruses derived from a different lineage from other dsRNA viruses. The second interpretation that was derived from the $\phi 8$ P1 structural determination reasoned that the protein was indeed similar to the corresponding reovirus coat proteins. This conclusion was reached notwithstanding the fact that reoviruses do not undergo particle expansion when the segmented dsRNA genome is packaged, as their coat proteins are already highly elongated.

P2

The P2 of cystoviruses exhibits RNA-dependent RNA polymerase (RdRP) activity catalyzing *de novo* initiation and elongation of replication and producing double-stranded RNA from single-stranded RNA templates. The crystal structure of the $\phi 6$ RdRP revealed that it is highly similar to that of Hepatitis C Virus (HCV) suggesting an evolutionary link even between double-stranded RNA viruses and flaviviruses. The basic architecture demonstrated that the $\phi 6$ polymerase resembles the hand-like features model in that the 664 amino acid residues of the monomeric protein form 25 α -helices and 21 β -strands whose 3-dimensional geometry is reminiscent of fingers, palm, and thumb in a human hand (Fig. 3(B)). The key aspartate residues characteristic of RNA polymerases are positioned analogous to that of the HCV polymerase. Co-crystallization of the $\phi 6$ RdRP with oligonucleotides resembling the 3' ends of the viral RNA templates showed that they bind within a tunnel lined with mostly basic amino acids that leads to an active site. A binding site in the substrate pore orders triphosphate moieties by their attachment to key basic residues. The observations suggested a mechanism whereby the incoming

Fig. 3 Structure of individual proteins and the assembly of $\phi 6$. The structure reconstructions are derived from cryo-electron microscopy and x-ray crystallography. (A) The $\phi 6$ P1 protein organized showing non-symmetrical dimers, P1A (red) and P1b (blue) (PDB #). The conformational mismatch of superimposed P1A and P1B is shown on lower part of the image. Symmetry mismatch of trapezoidal isomers allow for significant conformational change during packaging. (B) The $\phi 6$ P2 protein (PDB #1HHT, data were provided by Butcher, S.J., Grimes, J.M., Makeyev, E.V., *et al.*, 2001. A mechanism for initiating RNA-dependent RNA polymerization. *Nature* 410, 235). The arrow indicates the RNA template tunnel entrance. The cut-through rendering of the 3D structure shows the internal organization of RNA template tunnel and substrate pore. (C) The $\phi 6$ P4 protein (PDB #5MUV, data provided Sun, Z., El Omari, K., Sun, X., *et al.*, 2017. Double-stranded RNA virus outer shell assembly by bona fide domain-swapping. *Nature Communication* 8, 14814–14814). A hexameric toroid built of six identical subunits is localized around 5-fold axis of symmetry, which creates a symmetry mismatch. The top and side views are shown. The monomer of the $\phi 6$ P4 is shown with the N- and C-terminus indicated. (D) The $\phi 6$ P7 protein localization within PC based on difference map between PCs mutants lacking different structural proteins. The central cut of the PC complex shows the localization P2-P7 complexes at 5-fold axis proximity. P2 protein shown in green, P7 – in red. P2 density is blue and P4 toroid are in cyan. Magnified section showing P2 surrounded by three P7 monomers and an insert showing docked atomic model of P7. Data reproduced from Katz, G., Wei, H., Alimova, A., *et al.*, 2012. Protein P7 of the cystovirus $\phi 6$ is located at the three-fold axis of the unexpanded procapsid. *PLoS ONE* 7 (10). (E) The average $\phi 6$ P8 trimers, rendered as solid isosurface or mesh. Green rods are α -helices. The top and side views are shown. Data reproduced from Huiskonen, J.T., de Haas, F., Bubeck, D., *et al.*, 2006. Structure of the bacteriophage $\phi 6$ nucleocapsid suggests a mechanism for sequential RNA packaging. *Structure* 14, 1039–1048.

double-stranded RNA is unwound and fed through a template site to an active site, while nucleotides enter through a substrate pore. P2 is found closer to the 3-fold axis of symmetry in the unfilled PC. Cryo-EM data strongly suggests that the RdRP moves to the 5-fold axis upon RNA packaging and PC expansion.

P4

The cystoviruses package their own mRNA into the PC and the energy for this translocation activity is provided by the P4 NTPase. This protein is a hexamer, and when assembled on each of the twelve 5-fold axes on the PC, creates a symmetry mismatch (Fig. 3(C)). The initial x-ray diffraction high-resolution structure was first determined for the ϕ 12 P4 and subsequently for ϕ 6, ϕ 8, and ϕ 13. The six identical P4 subunits are arranged in a ring and resemble a domed toroid (Fig. 3(C)). Six ATP binding sites are located near the external perimeter of the ring at interfaces between adjacent subunits. The quaternary structure of the P4 toroid is similar to other hexameric helicases and the ϕ 8 and ϕ 13 examples both have 5'-3' RNA-helicase activity. The hexameric conformation contains a central region through which the mRNA being packaged is translocated. In addition there is a loop in each monomer found to be central within the hexamer structure. This loop is involved in the RNA translocation and is known to bind NTPs. Only one P4 – based portal is thought to sequentially package the three RNA segments. This could be the statistical consequence of a low occupancy of P4 on the unexpanded procapsid. The tenuous connection between P4 C-terminal and P1 is likely stabilized when all three genome segments are packaged, replicated and the P8 matrix assembles on the mature NC. Thus the fully assembled NC contains all of the twelve P4 hexamers.

P7

The P7 protein is the least characterized of the PC proteins in regard to precise function but *in vivo* studies demonstrate that it is essential for virus viability. P7 has been referred to as an accessory packaging factor but it is conceivable that this protein plays a direct role in RNA translocation and RNA packaging. The ϕ 12 P7 crystal structure was resolved at 1.83 angstroms for the N-terminal portion of the protein. P7 forms a novel α/β fold and measurement of solution NMR relaxation rates, chemical cross-linking, and static light scattering studies show that it exists in the dimeric form in solution (Fig. 3(D)). P7 has a C-terminal tail that is extremely flexible and *in vitro* assembly studies showed that incorporation of the protein stabilizes, and in ϕ 6, greatly enhances the rate of the PC assembly. As the PC is filled with the viral genome the PC undergoes expansion and as noted above the hinge of this conformational change lies along the two-fold axis, where P7 was postulated to exist as an elongated dimer at the interface between two P1 dimers. It was considered that the flexible C-terminal tail of P7 plays a role in inducing the P1 conformational change acting as the molecular hinge. Yet the position and function of the P7 packaging factor remain controversial. Cryo-EM studies of the unfilled ϕ 6 PC suggest that the P7 density overlaps the P2 density implying mutual exclusion of each protein at an inner 3-fold axis. However, difference maps generated between PC reconstructions and mutants lacking either P2 or P7 strongly suggest that P7 stabilizes P2 at the inner three-fold axis prior to RNA packaging. This implies P2 and P7 can interact and that they are located near each other in the vicinity of the inner 3-fold axis prior to packaging. Single particle reconstructions of the mature ϕ 12 NC strongly suggest that the P7 dimer is subsequently located at the portal 5-fold axis of symmetry surrounding the P4 NTPase hexamer.

P8

The addition of the P8 matrix to the genome filled PC completes the viral core maturation process and the arrangement of trimers of P8 determine the architecture of the NC. The NC matrix contains two types of holes, designated I and II with 60 of each type based on the arrangement of trimers of P8. In the ϕ 6 T = 13 lattice there are four classes of interdigitating P8 trimers termed Q, R, S, and T with Q closest to the 5-fold axis of symmetry (Fig. 3(E)). The five-fold axis of the P8 layer of the NC is occupied by the hexameric P4 packaging protein. In ϕ 12 the T = 13 lattice is considered to be incomplete in that a missing P8 density is occupied by densities corresponding to P7 dimers that surround the P4 hexamer. In ϕ 6 two states of the P8 trimer were identified as either open or closed. Shifting between the two states of the P8 trimers swap domains (or interdigitate) in order to stabilize the outer shell.

Membrane Envelope

The third, outermost, layer of the cystoviruses is a lipid bilayer. The viruses are 20% lipid by weight and constitute enough to cover approximately 50% of surface of the particle; the vacancies composed of the envelope protein. The ϕ 6 lipid bilayer contains phospholipids derived from the host plasma membrane and includes four virally encoded integral membrane proteins, P6, P9, P10, and P13. P3 forms an external spike that binds the host receptor and is anchored to the bilayer by P6. In the viruses that bind the host RLPS, the envelope also originates from the host cell membrane but the surface attachment proteins differ substantially from ϕ 6, reflecting the different host-cell attachment mechanism. Nevertheless, in all cases, P6 appears to anchor the P3 complex to the membrane and is also able to mediate membrane fusion releasing the uncovered NC into the periplasmic space. P12 is a non-structural protein that mediates membrane acquisition during assembly of the ϕ 6 viral particle and presumably does the same for other cystoviruses.

Fig. 4 The $\phi 12$ attachment P3 protein complex. The complex consist of six globular copies of P3a and three copies of P3c. Data reproduced from Leo-Macias, A., Katz, G., Wei, H., *et al.*, 2011. The toroidal surface complexes of bacteriophage $\phi 12$ are responsible for host-cell attachment. *Virology* 414 (2), 103–109.

Host Cell Attachment Complex

The $\phi 6$ spike protein, P3, extends from the viral outer envelope where it is anchored to the integral membrane protein P6. The P3-P6 complex constitutes the viral attachment apparatus that binds to type IV pili of the host cell to initiate infection and the pilus contracts to bring the virus particle to the outer cell membrane (OM) (Fig. 5). The $\phi 8$, $\phi 12$, and $\phi 13$ outer surfaces differ radically from that of $\phi 6$, $\phi 8$, $\phi 12$ and $\phi 13$ which bind to a truncated LPS O chain to initiate host cell infection. The $\phi 12$ attachment protein complex has been analysed in detail and is of a toroid shape consisting of six globular domains with six-fold symmetry (Fig. 4). Each of the globular domains is likely composed one copy of protein P3a and three copies of protein P3c. In all the species, once delivered to the host cell OM, the viral envelope fuses with that of the host using the fusogenic protein P6.

Genome Organization and Sequence Similarity

The *Cystoviridae* have three dsRNA segments that are designated according to the size as L (large, with 6374 base pairs in $\phi 6$), M (medium, with 4063 base pairs in $\phi 6$), and, S (small, with 2948 base pairs in $\phi 6$) (Fig. 6). Each virion particle contains only one copy of each segment and the genes are clustered into functional groups. Each genomic segment is transcribed into a polycistronic mRNA that is designated by a corresponding lower case letter. The genes encoding the PC are located on the L segment in the order *gene 7*, *gene 2*, *gene 4*, and *gene 1*. *Gene 14* precedes *gene 7* and the function of its protein product remains incompletely described. While in most members of the *Cystoviridae* the order of the L segment genes is 14, 7, 2, 4, and, 1; in $\phi 8$ the order is 14, H, 2, 4, 1, and 7. The H region is composed of a pair of genes, *Ha* and *Hb* in which the latter is required for temporal control of the 1 transcript (see below). In $\phi 6$ the production of the RNA polymerase P2 is down-regulated to approximately 10% the level of the other three PC proteins by translational coupling to the P7 gene, as *gene 2* lacks a ribosome binding site. The medium segment carries the genes 10, 6, 3, and, 13. *Genes 6* and 3 are in a polar relationship with each other as mutants lacking production of one suppresses the expression of the other. *Gene 3* encodes a single polypeptide in $\phi 6$, P3, whereas in $\phi 12$, *gene 3* encodes at least two proteins, P3a and P3c. The presence of two ORFs encoding P3 is also observed in $\phi 8$ and $\phi 13$, which like $\phi 12$ recognize RLPS as a host-cell receptor. This observation suggests that the oligomeric P3 complex extending from the viral surface uniquely encodes host cell specificity (see below). For each virus member, each of the three segments has a short, highly conserved sequence at the 5'-end (*i.e.*, designated from the plus sense strand of the dsRNA). The highly conserved sequence is followed by a unique packaging sequence that identifies each segment and ensures that it is packaged in the PC.

In 2018, a detailed phylogenetic analysis of each of the genomic segments for the characterized cystovirus types was conducted and the degree of relatedness established. The analysis allowed the diagramming of phylogenetic trees showing the relationships among each of the three genomic segments for the characterized virus types. Notably the phages $\phi 6$ and ϕNN were found to have significant nucleotide sequence similarity in the S and L segments and the proteins encoded are nearly identical. Greater diversity was seen in the M segment possibly reflecting the host range adaptation due to distant habitats. Overall a taxonomic description for the *Cystoviridae* was achieved and in regard to genome characteristics (such as GC content, gene organization, and gene synteny) there is a great similarity. It was proposed that based upon criteria of 95% nucleotide sequence identity for the demarcation of species in the *Cystoviridae* family, phages $\phi 8$, $\phi 12$, $\phi 13$, $\phi 2954$, ϕNN , and ϕYY can be classified as distinct species.

Replication Cycle

The entire cystovirus replication cycle is represented schematically in Fig. 5. While the host cell-viral P3 attachment mechanism (Fig. 5(A) and (B)) is either via the pili or RLPS (depending on the specific cystovirus) the remaining steps are for the most part the same in all the classified types.

Plasma Membrane Penetration and NC Entrance into the Cytoplasm

The integral membrane protein P6 facilitates the membrane fusion of the viral envelope with that of the host OM. The NC is then able to enter the periplasmic space and the peptidoglycan layer is digested by endopeptidase protein P5 that is loosely associated

Fig. 5 The $\phi 6$ replication cycle (in details of each step are in the text). (A, B) P3 attached to the pili, followed by pili retraction; (C) viral envelope fusion with OM; (D) $\phi 6$ NC entry into intracellular vesicle; (E) viral core release into the cytoplasm, P8 disassembly and initiation of transcription; (F) procapsid self-assembly; (G) packaging initiation in the order +s, +m, +l and PC expansion; (H) + strand RNA replication to the dsRNA genome; (I) P8 matrix loosely assembled around PC; (J) cell-derived bi-lipid membrane incorporated into the virion structure, followed by cell lysis and virion release.

Fig. 6 The three RNA segments of $\phi 6$ and genes encoding the proteins.

on the NC (**Fig. 5(C)**). The NC penetration is mediated by the P8 lattice which interacts with the host cytoplasmic membrane resulting in containment of the NC in an intracellular vesicle (**Fig. 5(D)**). The viral core is released into the host cytoplasm and the P8 lattice disassembly initiates viral genome transcription (**Fig. 5(E)**).

Transcription

Once within the host cell cytoplasm, the NC transcribes the three dsRNA genomic segments to produce the message sense l, m, and s strands that are expelled from the particle (**Fig. 5(E)**). Transcription functions by a semiconservative strand displacement mechanism in which the nascent plus strand that is displaced replaces the original one which is released from

the NC. In $\phi 6$, transcription initially produces equimolar concentrations of all of the three segments. However translation of the l transcript is favored which allows assembly of new unfilled PC particles early in the infection. Later in the replication cycle, the l transcription level is reduced to 5%–10% of the initial concentration and translation of m and s predominates. The mechanism that regulates the temporal control of cystovirus transcription is incompletely understood but has been partially elucidated for $\phi 6$ and $\phi 8$. In $\phi 6$ the 5' 18-base sequences of the three-plus sense strands are identical with the exception that the m and s begin with GG while l begins with GU. The GU acts to signal the control the altered transcription profile of the l message RNA. Isolated of PC particles containing dsRNA and primed for transcription were found to contain a host cell-derived protein, YajQ, that influenced temporal control of transcription by increasing l production. YajQ does not directly activate the P2 polymerase but was found to bind the PC framework protein P1. Phage $\phi 2954$ has adapted to utilize host cell protein glutaredoxin 3 (GrxC) for the activation of L segment transcription and mutations that resulted in GrxC transcription independence were found in the gene for protein P1. In $\phi 2954$ (and $\phi 12$) the 5' end of the L segment begins with ACAA as an identifier while the S and M segments begin with GCAA (GAA in $\phi 12$). In $\phi 8$ the level of l transcription is independently controlled, without the need of a host cell protein. The three $\phi 8$ 5' plus sense RNA ends have short consensus sequences in that only the first seven nucleotides are identical. Yet in spite of the absence of a 5' L sequence identifier late in the infection cycle the l message transcription is considerably lower than that of the m and s messages. A gene found on the 5' end L segment (see above) encoding product Hb acts with host cell RNase R to degrade excess l transcript and bring it down to a concentration required for the late infection phase.

PC Assembly and Packaging

The $\phi 6$ replicative mechanism starts with the assembly of the empty PC (Fig. 5(F)). This is followed by the specific selection and packaging of three segments of viral mRNA within the PC. The dodecahedral-shaped PC (Fig. 5(G) and (H)) contains the RNA packaging and replication apparatus at each of twelve portals constituting polymerase complex. The polymerase complex consists of P2, P4 and, based on cryo-electron microscopy reconstruction of the $\phi 12$ virus, P7. The viral mRNA strands are packaged in a specific size order and replicated to the double-stranded format utilizing P2 RdRP only after the packaging is completed (Fig. 5(H)). The P2 RdRPs are located at each of the 12 portals and appear to undergo a position shift from the three-fold axis to the five-fold axis after PC expansion. The PC undergoes a specific and sequential expansion during RNA packaging that selectively exposes RNA binding sites for each of the three RNA segments. The noncoding sequences at the genome 3' ends direct RNA replication and are discussed below.

NC maturation

After packaging and RNA replication, a matrix composed of 200 trimeric copies of protein P8, is assembled around the filled PC (Fig. 5(I)). The P8 matrix is an open structure which can allow passage of water, cations and other smaller molecules. The PC, P8, and genome together form the NC.

Membrane acquisition and host cell lysis

A lipid-bilayer-membrane envelope, derived from the *Pseudomonas* host-cell, is assembled around the NC (Fig. 5(J)). The mechanism of viral envelope assembly is not entirely understood. It involves the non-structural P12 protein which is not present in the completely assembled virion. The envelope contains four membrane proteins, P6, P9, P10, and P13, within a lipid bilayer. Based on cryo-electron microscopy of the $\phi 12$ virus, protein P5 is likely positioned between the NC and the envelope. P3 proteins form external spikes on the envelope whose function is to bind to the host cell receptor. After the entire virus is assembled host cell lysis releases approximately 150–200 virus particles. This process utilizes two lytic proteins, the P5 murein peptidase working in conjunction with a holin lytic factor P10 that destabilizes the host envelope.

Recombination and Reassortment

RNA strand recombination in cystoviruses is due to template switching and is not overly dependent on sequence similarity at the crossover point. Recombination occurs during minus strand synthesis of a plus sense template and is dependent on the conformation on the RNA 3' end. Replication recognition signals of the plus sense RNA consist of a secondary structure composed of stem-loops near the 3' ends and removing these structures facilitates recombination. The replication of the genome segment after deletion of the RNA 3' structure can only be restored if the template is rescued by recombination.

In addition to genetic exchange by recombination reassortment of the three genome segments occur among the cystovirus species. This mechanism can occur naturally or in the laboratory setting. Investigation of the rates of reassortment in both natural and laboratory types allows analysis of viral evolution in multi-stranded RNA viruses. Experimentally genetic exchanges have been visualized as altering whole virus electrophoretic mobility demonstrating a useful selectable phenotype in studies of viral evolution and fitness.

Carrier State

Under certain conditions, a ϕ 6 infection can produce a carrier state in which the virus replicates but does not cause lysis of the host cells and the phenomenon is often seen in viruses with mutant viral lytic factors. In the carrier state, the phage does not need to reinfect cells and can dispense with select genes. Essentially the viral genome replicates as an episomal element in the host cell cytoplasm. The carrier state can be extremely stable as when drug resistance selection is maintained. For example, a kanamycin resistance gene incorporated into the M segment- with host cell selection for the antibiotic- allowed the loss of the S segment. This carrier mutant clearly had altered the packaging order by dispensing with s that is normally the first viral mRNA packaged. These mutants had altered the P1 protein suggesting that RNA interaction and packaging order is dependent on the PC framework protein.

Reverse Genetics and Self Assembly

The advent of reverse genetics methods for both ϕ 6 and ϕ 8 represented the first example of the production of recombinant genetic methods for segmented dsRNA viruses. Initially, the ϕ 6 rescue system required the packaging of *in vitro* synthesized transcripts into a PC assembled in *E. coli* to which was added the P8 matrix. This particle was then transfected into *pseudomonad* spheroplasts and viable recombinant progeny recovered. This system demonstrated the feasibility of producing viable engineered segmented dsRNA virus particles, however, the *in vitro* assembly was not efficient. Subsequently, methods utilized electroporation of ϕ 6 and ϕ 8 cDNA plasmids carrying three genomic segments that were introduced directly into *pseudomonad* hosts. The host cells expressed either SP6 or T7 RNA polymerase that directed recombinant viral ssRNA transcription. The latter methodology has contributed to the understanding of the precise nature of the RNA packaging and replication signals and mechanisms for RNA segment recognition by the PC. The *in vitro* self-assembly of complete and partial PC particles has been achieved as well by condensation of the purified protein components. The particles were found to be capable of packaging the viral ssRNA via NTP hydrolysis, replication the dsRNA and subsequent transcription of nascent ssRNA. The self-assembly assay has facilitated the study of PC assembly kinetics and the precise protein stoichiometry in the particles.

Applications and Intellectual Property

Since the time of its discovery, ϕ 6 has been the subject of intellectual property applications. The observation that the phage contained dsRNA stimulated the filing and award of a patent in 1974 for the preparation of high yields of dsRNA for interferon production. In 2006 a patent was awarded for the rescue of recombinant ϕ 6 that carried cDNA for the expression of therapeutic genes encoding vaccine antigens, catalytic or antisense RNAs and immunoregulatory proteins. The claims of the invention suggested that the isolated recombinant phage NC could be induced to enter eukaryotic tissue where the bioreactive gene would be expressed by a cap-independent translation enhancer after transcription by the ϕ 6 P2 RdRP. While these two applications have not been brought to practice recombinant ϕ 6 P2 has been made commercially available. The RdRP, with its capacity for primer independent replication and transcription, have made it a useful tool for the synthesis of large RNA molecules and RNA-based sequencing.

Nomenclature

dsDNA Double-stranded DNA

ssDNA Single-stranded DNA

T Triangulation number

Glossary

DNA packaging Energy-requiring process where the empty virus capsid is filled by the virus genome.

Protein-primed DNA replication Duplication of a linear DNA genome utilizing a protein covalently linked to the DNA terminus to initiate the reaction.

Temperate Bacteriophage can either lyse the cell or enter a resting state called lysogeny, staying dormant within the cell until induced into lytic cycle.

Triangulation number, *T* number (*T*) A parameter defined for icosahedral viruses that describes the geometrical arrangement of the protein subunits within the capsid shell.

Virulent Bacteriophages lyse the cell releasing new viral progeny.

Introduction

The icosahedral bacterial viruses with an internal membrane can have double-stranded (ds) or single-stranded (ss) DNA genomes. Currently these viruses are classified into four families: *Tectiviridae*, *Corticoviridae*, *Matsushitaviridae* (previously in *Spherolipoviridae*), and *Finnlakeviridae* (Table 1). In addition, there are virus isolates not yet assigned to any family and a newly proposed family *Autolykiviridae*. The dsDNA genomes are either linear or circular, and the only known ssDNA phage with an internal membrane has a circular genome. They encompass both virulent and temperate viruses, their virions range from 49 nm to 80 nm in diameter and lack a tail but may exhibit a special vertex containing a DNA packaging machinery.

Tectiviruses form the most numerous group, and they are classified into three genera: *Alphatectivirus*, *Betatectivirus*, and *Gammatectivirus* (and a newly proposed *Deltatectivirus*) (Fig. 1). Members of the *Alphatectivirus* (PRD1 and PR4) are virulent phages of Gram-negative hosts (e.g., *Pseudomonas* and *Salmonella*). These viruses along with the four extremely similar phages (PR3, PR5, PR772, and L17) have linear dsDNA genomes. Their sequence similarity is between 91.9% and 99.8%, which is surprising since they have been isolated from different parts of the world. The viruses of the genus *Betatectivirus* are temperate phages (AP50, Bam35, GIL16, and Wip1) replicating in Gram-positive *Bacillus* species. The third genus *Gammatectivirus* has a single member, the first temperate tectivirus, GC1, with a Gram-negative host (*Gluconobacter*). The type virus of the *Tectiviridae* is PRD1, which infects a wide variety of Gram-negative bacteria. Its host range is limited to bacteria that contain a conjugative antibiotic resistance plasmid, since it utilizes the plasmid-encoded cell surface DNA-transfer complex as a receptor. Bam35 serves as a model virus for phages infecting *Bacillus* species. The length of the genomes (about 15 kbp) and the order of the genes is conserved in all the tectiviruses, but there is no significant sequence similarity between the two major groups (*Alphatectivirus* and *Betatectivirus*). The genomes of the tectiviruses encode about 35 proteins as exemplified by the PRD1 genes (Table 2).

The type virus of the family *Corticoviridae* is PM2. PM2 was isolated in 1968 from seawater off the coast of Chile along with its host, which is a marine bacterium *Pseudoalteromonas espejiana*. PM2 was the first membrane-containing bacteriophage isolated. PM2 has a negatively-supercoiled, circular dsDNA of about 10 kbp. It encodes about 17 proteins (Table 3). Recently, *Pseudoalteromonas* phage Cr39582 was induced from *Pseudoalteromonas* sp. strain Cr6751 and assigned to the family *Corticoviridae*. PM2 and Cr39582 have 85% nucleotide identity but their spike protein genes are non-homologous. The entry and the DNA-packaging mechanisms differ from those of tectiviruses with linear dsDNA genomes.

Thermus bacteriophages P23–77 and IN93 (species *Hukuchivirus* P23-77 and *Hukuchivirus* IN93) are members of the family *Matsushitaviridae* and were recently moved from the family *Sphaerolipoviridae* (Table 1). Flavobacterium phage FLiP with a circular ssDNA genome has been recently assigned to the new family *Finnlakeviridae*.

In addition, isolates of *Salisaeta* phage SSIP-1 and *Helicobacter pylori* phage KHP30 with circular dsDNA genomes are yet to be assigned families. These viruses share no significant sequence homology to any previously identified virus group. A group of 18, marine, virulent, non-tailed viruses with linear, dsDNA, 10 kbp genomes infecting members of the *Vibrionaceae* were recently identified and the family *Autolykiviridae* was proposed after phylogenetic analyzes (Table 1). The proposed *Autolykiviridae* members have 21%–25% amino acid identity to PM2 in their major capsid protein but the protein-primed DNA polymerase has 36%–37%

amino acid identity to members of the *Tectiviridae*. Large numbers of viruses with double jelly-roll major capsid protein have been detected in the genomes of diverse major bacterial and archaeal phyla, and in marine water column and sediment metagenomes, indicating that the diversity of this virus group greatly exceeds the diversity that is currently recognized (Fig. 2; Table 1).

The most studied model system in this group of viruses is bacteriophage PRD1, which is used here as an example to illustrate some of the most common characteristics of this diverse virus group.

Virion Structure and Properties

Overall Structure

The virion of PRD1 is an icosahedrally-symmetric particle approximately 65 nm in diameter (**Fig. 3**). It is composed of about 70% (mass fraction) protein, 15% lipid, and 15% DNA and has a mass of about 66 MDa. The structure of the virion has been studied

Table 2 PRD1 genes, corresponding proteins, and protein functions

extensively using cryo electron microscopy and X-ray crystallography (Fig. 3(a)). X-ray crystallography results have indicated the roles of four proteins in controlling virus assembly. There are 240 hexagonally shaped trimers of the major capsid protein, P3 (Fig. 4(a)), occupying the surface of the capsid on a pseudo $T = 25$ lattice (Fig. 3(a)), an arrangement that is also found in the human adenovirus capsid. The capsid protein fold and arrangement in the shell belong to the vertical β -barrel structural lineage (Fig. 4(c)) is common among viruses with an internal membrane not only bacterial viruses but also archaeal (STIV, STIV2) and eukaryotic viruses (PBCV-1) having one double β -barrel MCP. In addition, phages (P23-77, the family *Matshushitaviridae*) and archaeal viruses (SH1, HCIV-1, HHIV-2, the family *Sphaerolipoviridae*) have two major capsid proteins obeying vertical single β -barrel fold, thus belong also to the vertical β -barrel structural lineage. In PRD1, a dimer of the linear glue protein P30 extends

Fig. 2 Diversity of viruses exhibiting the double jelly-roll (DJR) major capsid protein. (a) Phylogeny of bacterial and archaeal DJR virus capsid proteins. Group numbers are assigned to each branch for reference, colored blocks indicate hosts, black circles on branches indicate approximate likelihood-ratio test branch support ≥ 0.9 . (b) Element gene diagrams from each group show prophage host genome neighborhoods and metagenome contigs often contain additional genes common to DJR elements. (G +, Gram-positive; G –, Gram-negative hosts). Reprinted with permission from Kauffman, K., Hussain, F.A., Yang, J., *et al.*, 2018. A major lineage of non-tailed dsDNA viruses as unrecognized killers of marine bacteria. *Nature* 554, 118–122. © 2018 Springer Nature.

from one vertex to the next, cementing the P3 facets together (Fig. 4(b)) and determining the overall size of the shell. Eleven of the vertices are composed of the pentamer penton protein P31, which interlock with P3 and the transmembrane protein P16 forming the base for the spike complex (Fig. 3(b)).

The receptor binding vertices have two proteins attached to the penton: one is a trimer of P5 (Fig. 5(a)) attached by the N-terminus, the other is a monomer of P2 (Fig. 5(b)), the receptor-binding protein. Both P5 and P2 are elongated molecules (P5 is 17 nm long, P2 is 15.5 nm long). P2 is a club-shaped molecule with a pseudo β -propeller head and a long tail formed from extended β -sheet. The head is proposed to be the site of receptor binding, lying distal to the virus.

The twelfth PRD1 vertex is the unique or special vertex used for genome packaging and DNA delivery (Figs. 3(b) and 6). At the unique vertex, the capsid and the internal membrane are interconnected by a hexamer composed of heterodimers of proteins P20 and P22 and serves as a membrane conduit for the genome and as a nucleation site for the special vertex assembly. The outer part of the unique vertex is formed of a complex of packaging ATPase P9 and packaging efficiency factor P6 (Fig. 6(c)). When the packaging starts, protein P9 is recruited to the procapsid and the PRD1 genome with the terminal protein P8 is packaged into the procapsid powered by ATP hydrolysis. The packaging ATPase P9 is part of the mature virion in contrast to the packaging ATPases of tailed dsDNA bacteriophages.

The overall size and structure of the phage Bam35 is very similar to that of PRD1. However, the exact counterparts of many of the PRD1 structural proteins have not yet been clearly identified. Two of the major differences between PRD1 and Bam35 are firstly, the presence of a large transmembrane protein complex in Bam35 that modulates the curvature of the membrane under the capsid facets, and secondly, the receptor-binding proteins of the attachment vertices.

The corticovirus PM2 particle is icosahedrally-symmetric and measures 57 nm in diameter from vertex to vertex. The mass of the virion is ~ 45 MDa and it is composed of protein (72%), lipid (14%), and DNA (14%). The capsid is composed of 200 trimers

Fig. 3 (a) Cryo-electron microscopy reconstruction of PRD1 virion. One facet of the $T = 25$ capsid is delineated together with position of the symmetry axes. of the MCP P2 arranged on a pseudo $T = 21$ lattice. Pentameric receptor-binding spikes protrude from the vertices (Fig. 5(c)). The receptor binding domain of the spike is structurally related to the PRD1 P5 head domain (Fig. 5(a) and (c)).

Membrane and DNA

In PRD1, about half of the virion proteins are associated with the membrane (Table 2). The lipid headgroups are predominantly phosphatidylethanolamine (53%) and phosphatidylglycerol (43%) with 4% of cardiolipin. The membrane is well-ordered, following the icosahedral outline of the capsid. Many interactions occur between the membrane, the capsid and the DNA. The average separation of the concentric layers of DNA is approximately 2.5 nm, similar to that found in other bacteriophages and animal viruses. Removal of the capsid and spike proteins by heat or guanidinium hydrochloride treatment results in aggregation of the membrane vesicle.

In PM2, the membrane, lying underneath the capsid, follows the shape of the capsid as in PRD1, and there are many interactions mediated by the major membrane proteins P3 and P6 (Table 3). The lipid composition is approximately 64% phosphatidylglycerol, 27% phosphatidylethanolamine, and 8% neutral lipids and a small amount of acyl phosphatidylglycerol. Release of the capsid and spike proteins from the virion by freeze–thawing or by chelation of calcium ions with ethylene glycol tetraacetic acid (EGTA) results in a soluble vesicle called the lipid core.

Life Cycle

PRD1 is a virulent phage that exploits the transcription functions of its host. The host cell is selected by specific recognition of a plasmid-encoded cell surface receptor with its primary function in bacterial conjugation. PRD1 belongs to the class of broad-host-range, donor-specific phages, which infect cells harboring one of the IncP-, IncN-, or IncW-type multiple-drug resistance

conjugative plasmids. Among the hosts are several opportunistic human pathogens such as *Escherichia coli*, *Salmonella enterica*, and *Pseudomonas aeruginosa*. After adsorption, the genome is injected into the host cell cytosol with the help of the inner membrane, leaving the protein capsid outside. After the replication of the phage genome and production of the phage components, both virus- and host-encoded factors assist in particle assembly. Host cell lysis releases some 500 progeny viruses. Bam35 is a temperate phage, that can have a lytic life cycle like PRD1, or exist in a dormant state within the host (lysogenic life cycle). In contrast to PRD1, the host range of Bam35, and its relatives GIL01 and GIL16, is limited to one species, *Bacillus thuringiensis*. AP50 infects *Bacillus anthracis*, and a defect phage replicating as a linear plasmid (pBClin15) has been described for *Bacillus cereus*. The corticovirus PM2, P23–77 phage of *Thermus thermophilus*, SSIP-1 phage of *Salisaeta* species, the *Vibrio* phages are virulent viruses. *Thermus* phage IN93 and *Streptomyces* phages WheelHeim and Forthebois are temperate phages. Of all the DNA phages with an internal membrane, the life cycle of PRD1 is best understood and is described below.

Receptor Recognition and DNA Delivery

A single phage structural protein, P2, is responsible for PRD1 attachment to its host. Each of the eleven receptor recognition vertices is a metastable structure and possibly capable of recognizing the receptor. After binding to the receptor, the particle most probably re-orientes (possibly guided by secondary binders e.g., protein P5) so that the unique vertex is perpendicular to the cell surface. The association of P2 with the receptor activates, possibly by receptor binding complex removal, the injection process. This leads to irreversible binding. Both empty and DNA-containing particles are bound equally tightly to cells, indicating that DNA injection is not a prerequisite for this tight interaction.

Isolation and analysis of PRD1 mutants have resulted in the identification of eight, phage-specific, structural proteins essential for infectivity and DNA delivery. In addition to the spike complex proteins (P2, P5, and P31 especially P2 needed for adsorption), protein P11 starts the DNA delivery process and membrane proteins P14, P18, and P32 are involved in later stages of the DNA delivery. Mutant particles missing protein P7 (a lytic transglycosylase) are infectious but the DNA entry process is delayed. The PRD1 membrane undergoes a structural transformation from a spherical vesicle to a tubular form which penetrates the host cell envelope and acts as a conduit for DNA delivery. DNA ejection tube protrudes from the unique vertex used for DNA packaging. The packaged genome (DNA-P8 complex) does not have a role in the triggering or in the formation of the DNA delivery tube, since also procapsids devoid of the packaged genome can form tubes. Similar tube formation is typical for all members of the *Tectiviridae* and also seen in the *Vibrio* phages, but not recognized in other virus isolates representing internal membrane-containing DNA phages.

Genome Replication

The genome of PRD1 is a linear dsDNA molecule with proteins covalently (protein P8) attached to both 5' termini and having 110 bp terminal repeats. PRD1 replicates its DNA by a protein-primed replication mechanism similarly to other viruses with linear dsDNA genomes, including adenovirus and the ϕ 29-type phages. PRD1 DNA replication starts with the formation of a covalent bond between the genome terminal protein, P8, and the 5' terminal nucleotide, dGMP, in a reaction catalyzed by the phage DNA polymerase (protein P1). The minimal origin of replication resides in the 20 first-terminal base pairs of both genome ends, and the fourth base from the 3' end of the template directs, by base complementation, the linking of deoxyribonucleoside monophosphate (dNMP) to the terminal protein. The 3' end DNA sequence is maintained by sliding back of the polymerase complex.

After initiation, elongation of the initiation complex by the same DNA polymerase takes place resulting in the formation of full-length daughter DNA molecules. Two phage-encoded ssDNA binding proteins, P12 and P19, are involved in replication in vivo.

Particle Assembly

Approximately 15 min post infection, the major capsid protein P3 and the spike complex proteins P2, P5, and P31 are found soluble in the host cell cytosol, whereas the phage-encoded membrane proteins (e.g., P7, P11, P14, and P18) are associated with or inserted into the host cell cytoplasmic membrane (CM). Correct folding and assembly of several viral proteins are dependent on the host GroEL/ES chaperonins. Upon assembly, a virus-specific patch from the host CM is pinched off by the forming procapsid using the membrane-bound scaffolding protein P10. In addition, two small phage-encoded non-structural proteins P17 and P33 function in the assembly process, possibly in association with the host chaperonin complex GroEL/GroES.

Correct assembly results in an empty capsid enclosing a membrane rich in phage-specific proteins (procapsid). The linear dsDNA genome is packaged into the prohead by the packaging ATPase P9. Unlike packaging ATPases of most other icosahedral dsDNA bacteriophages, P9 is part of the mature virus structure. It resides at a single vertex that also contains proteins P6, P20, and P22. P6 is a soluble protein needed for efficient DNA packaging and the latter two are integral membrane proteins connecting the portal structure to the viral membrane.

Cell Lysis

At the end of the infection cycle, the newly synthesized progeny virions are released via host cell lysis. A two-component, holin–endolysin system operates in phage PRD1. The endolysin protein, P15, is a soluble β -1,4-N-acetylmuramidase that degrades the peptidoglycan of the Gram-negative cell causing host cell lysis. The holin protein, P35, is a helper factor that makes pores in the inner membrane to facilitate the access of the endolysin to the peptidoglycan in the cell wall, controlling the timing of lysis. In addition, PRD1 has accessory lysis proteins P36 and P37 that function as a pair (spanins) which is an interchangeable analog of the Rz/Rz1 of bacteriophage lambda. Spanins act after cell-wall degradation, aggregating and causing the disruption of the outer membrane.

Genomes and Genomics

The length of the PRD1 genome is 14,927 bp and the guanine–cytosine (GC) content is 48.1%. It has 110 bp-long inverted terminal repeat (ITR) sequences at the ends, which are 100% identical. The majority of the PRD1 ORFs products have been identified and currently there are 27 known genes (Table 2). The genomes of the other Gram-negative bacteria-infecting tectiviruses are similar, varying between 14,935 and 14,954 bp, and exhibit remarkably conserved nucleotide sequences, the overall identity being 91.9%–99.8%. The Bam35 genome is 14,935 bp long with a GC content of 39.7%. The ITRs are 74 bp long with only 81% identity between the ends. PRD1, Bam35, and GC1 (representatives of the three genera of *Tectiviridae*) do not share much sequence similarity (Fig. 1). The discovery of the almost invariant genomes within the tectivirus groups contrasts sharply with the situation observed for the tailed dsDNA bacteriophages. The nucleotide identity is 100% between Bam35 and the related GIL01 and 83% between GIL01 and GIL16.

PRD1 genome is organized into two early and three late operons. Although there are no major sequence similarities between PRD1, Bam35, and GC1 genomes, common genes for DNA polymerase, packaging ATPase, muramidase, transglycosylase lytic enzyme, and major capsid protein can be recognized by corresponding conserved amino acid sequence motifs in the databases or identified by comparing the N-terminal amino acid sequence of the major virion protein to the DNA sequence. Typically, the genes responsible for the host cell recognition (the spike protein) are the most diverse even between closest viruses.

The circular PM2 genome is 10,079 bp long with a GC content of 42.2%. It contains 21 putative genes, of which 17 have so far been shown to be functional (Table 3). Promoter mapping by primer extension has revealed three operons, which are expressed in a timely fashion during infection. The first early operon is highly similar to the maintenance region of the *Pseudoalteromonas* plasmid pAS28. The second early operon contains genes for DNA replication and regulation of late phage functions.

The PM2 genome replicates via a rolling-circle mechanism. Protein P12 has conserved sequence motifs common to superfamily I replication initiation proteins. This superfamily consists of the A proteins of certain bacteriophages, such as ϕ X174 and G4, and the initiation proteins of cyanobacterial and archaeal plasmids. The function of the late operon is activated by two phage-encoded transcription factors, P13 and P14. P14 has sequence similarity to the TFIIIS-type general eukaryotic transcription factors most closely resembling those of the archaeal organisms *Thermococcus celer* and *Sulfolobus acidocaldarius*.

The structural proteins, encoded by the late genes, are similar to the corresponding proteins of tectiviruses, either membrane associated or soluble. Based on the conserved amino acid sequence motifs deduced from the nucleotide sequence, one of the structural virion proteins is a putative packaging ATPase. The packaging process of the circular supercoiled PM2 DNA is coupled with the formation of the particle.

Glossary

Capsid or Head The protein container for the Caudovirales phage genome, usually icosahedral in shape, that protects it from the environment until it is delivered to a new host.

Contractile tail The tail type that defines the Myoviridae, composed of a baseplate that contacts the host surface, an outer protein cylinder or sheath and an inner tail tube or core. When a host is bound the sheath contracts driving the tube into the cell to deliver the genome to the host.

DNA packaging The energy-driven process by which a procapsid is filled with phage DNA to become a mature capsid.

GenBank The United States National Institutes of Health genetic sequence database, an annotated collection of all publicly available DNA sequences.

Horizontal gene exchange Transfer of genetic material between different species.

Portal A grommet-like ring composed of 12 copies of the portal protein that occupies one capsid vertex, and

through which DNA is packaged and to which the tail is attached.

Procapsid or Prohead An immature capsid that has a spherical shape and contains no DNA.

T number The Triangulation number (T), a formal descriptor for complex icosahedral structures that describes the geometric arrangement of subunits for a viral capsid. The number of capsid protein subunits is $\sim 60 \times T$.

Tail The part of the virion responsible for attachment to the host and genome injection that is attached to one vertex of the capsid, at the portal.

Tail fiber An elongated protein fiber attached to a phage tail that helps recognize a host by binding to the host by the tip of the fiber.

Virion The entire Caudovirales viral particle composed of a capsid containing the viral genome, tail, tail fibers and other appendages.

Introduction

The icosahedral tailed double-stranded DNA bacterial viruses or bacteriophages of order *Caudovirales* are among the most widely recognized icons of modern molecular biology. Anyone who has participated in an advanced biology, genetics, or molecular biology class is likely to have been exposed to images of the lunar-lander-shaped bacteriophage T4 virion (family *Myoviridae*) with its elongated icosahedral capsid and machine-like contractile tail (Fig. 1(A)) or the plain icosahedral capsid and elegant, gently curving tail of bacteriophage λ (family *Siphoviridae*, Fig. 1(B)). Both T4 and λ are bacteriophages that infect the enteric bacterial host *Escherichia coli* and have been studied extensively. Bacteriophages were originally discovered in the early 20th century (1915–17) by English microbiologist Frederick W. Twort, and French-Canadian microbiologist Felix d'Herelle. Although there was much early interest in bacteriophages because of their potential for use in treating bacterial diseases (phage therapy), research on bacteriophages for disease therapy was largely abandoned after the discovery of antibiotics. Bacteriophage research was revived in the 1940s by Max Delbrück and colleagues (the well-known Phage Group that often met at the Cold Spring Harbor Laboratories on Long Island, NY) and the focused phage research started by this group of scientists led to many fundamental biological discoveries during the birth of molecular biology. The modern emergence of multiply antibiotic resistant strains of human pathogens has rekindled an interest in developing phage therapy as a means of treating human, fish, insect (bees) and livestock diseases.

The Structure of Tailed dsDNA Bacteriophages

The invention and commercialization of the electron microscope led to the first images of phages as sperm-like particles with a head and tail using metal shadowing, in which images were formed by heavy metal atoms such as uranium that were evaporated in a vacuum and allowed to strike a dried phage specimen at an angle. The later introduction of negative stains (salts of heavy metals that dry as a thin layer without forming crystals and in which small particles such as phages could be embedded) for electron microscopy resulted in images that were far richer in detail than earlier methods and revealed the complexity and variety of phage morphology. Fig. 1 shows electron micrographs of phages T4 and λ made using the negative stain technique. Cryo-electron microscopy of frozen hydrated phage samples is the latest innovation and is capable of revealing near-atomic details of phages and their structural components. Electron microscopy has remained a major tool in the study of bacteriophages and, in fact, the current taxonomic system for phages relies heavily on phage morphology as determined by electron microscopy as a major discriminating factor. Table 1 shows a taxonomic table for order *Caudovirales* and some of their characteristics. *Myoviridae* have contractile tails and include bacteriophages T4 (Figs. 1(A) and 2) and P1. *Siphoviridae* have long non-contractile tails and include phages λ (Fig. 1(B)) and T5. *Podoviridae* have shorter stubby or stumpy tails and include phages P22 and T7. The utility of morphological classification as a basis for phage taxonomy has more recently come into question as new insights

Fig. 1 Electron micrographs of two bacteriophages. (A) Bacteriophage T4. (B) Bacteriophage Ur- λ . Ur- λ is the original phage λ isolate and has the side tail fibers that are missing in the λ strains that are widely used. The micrographs were made using the negative stain Uryanyl acetate to embed the phage particles and provide contrast. The samples appear lighter than the enclosing stain.

Table 1 Tailed dsDNA bacteriophages: Order *Caudovirales*

Family	Genus	Defining example	Capsid T-number	Genome size bp
<i>Myoviridae</i> (phages with contractile tails)	"T4-like viruses"	Enterobacteria phage T4	T = 13; Q = 20	168,903
		Bacillus phage G	T = 52	497,513
	"P2-like viruses"	Enterobacteria phage P2	T = 7	33,593
	"PhiKZ-like viruses"	PhiKZ	T = 27	280,334
	"Mu-like viruses"	Enterobacteria phage Mu	T = 7	36,717
	"SP01-like viruses"	Bacillus phage SP01	T = 16	~132,500
<i>Siphoviridae</i> (phages with thin non-contractile tails)	" ϕ H-like viruses"	Halobacterium virus ϕ H	T = 7?	~57,000
	" λ -like viruses"	Enterobacteria phage λ	T = 7	48,502
	"T1-like viruses"	Enterobacteria phage T1	T = 7?	48,836
	"T5-like viruses"	Enterobacteria phage T5	T = 13	121,750
	"c2-like viruses"	Lactococcus phage c2	T = 4?; Q = 7?	22,172
	"L5-like viruses"	Mycobacterium phage L5	T = 7	52,297
	" ψ M1-like viruses"	Methanobacterium ψ M1	?	~23,246
	"T7-like viruses"	Enterobacteria phage T7	T = 7	39,937
<i>Podoviridae</i> (phages with short stubby tails)	" ϕ 29-like viruses"	Bacillus phage ϕ 29	T = 3; Q = 5	19,366
	"P22-like viruses"	Enterobacteria phage P22	T = 7	41,724

into phage evolution have revealed that horizontal exchange of genes is widespread among phages, and further, that some structural genes of bacteriophages and viruses that infect organisms from other domains of life appear to share common ancestors.

Bacteriophage Structure and Function

Capsids

In the dsDNA bacteriophages, the capsid serves as the container for the DNA chromosome and protects it from the environment until it is delivered to a new host by the phage tail, the organelle of attachment and genome delivery. In many other types of viruses, the capsid is taken up by cells with the genome still inside, and the virus particle uncoats or disassembles within the new host to initiate viral replication. The dsDNA bacteriophages capsids do not have to disassemble in this manner to initiate infection, so they can be constructed to be highly stable – resistant to a wide variety of chemical and physical assaults from the environment and digestive tracts – as they travel from one host to another. The dsDNA genome in bacteriophage capsids is packed to a very high density (~ 0.5 g/ml), so the capsid shell has to be strong enough to contain this tightly packed and highly concentrated DNA. Most of the *Caudovirales* have symmetric icosahedral capsids, but some have capsids with an elongated icosahedral shape, like T4 (Figs. 1(A) and 2) that have icosahedral ends with an elongated tubular middle section in between.

Fig. 2 Structural features of a typical bacteriophage. A drawing of a bacteriophage with a contractile tail, like phage T4. Many of the structural components that are discussed in the article are labeled.

Tails and Tail Fibers

Phage tails function to identify and bind to the correct host and to deliver the phage genome into that new host to initiate replication. Phage tails have a large variety of morphological forms with many parts and appendages, such as those labeled on the diagram of T4 in [Fig. 2](#) and visible in the electron micrograph in [Fig. 1](#). We know little about the functions of some tail parts, but others are understood in considerable detail. For example, in bacteriophage T4, both the long tail fibers and the short tail fibers (which are folded under the baseplate until after the long tail fibers are bound to the host – see [Fig. 2](#)) recognize specific host receptors. The long tail fibers of phage T4 are the primary determinants of host range, and mutations that change the T4 host range cause alterations in the fibers near their distal tips. The whiskers that are attached to the top of the T4 tail have multiple functions. The whiskers act as assembly jigs for adding the long tail fibers to the virion, and they also act as environmental sensors that sequester the long tail fibers under unfavorable conditions and thus prevent attachment to a host.

The long tail fibers of T4 have an analog in bacteriophage λ , but in the ordinary laboratory strains of λ , these fibers are not made because of a mutation in the side tail fiber gene. The electron micrograph in [Fig. 2](#) shows the long side tail fibers present on Ur- λ , a primordial λ that lacks this mutation. These long side tail fibers of Ur- λ speed up the adsorption of this phage to its host, but are not required for infection, because the primary interaction of λ with its host is mediated by the central tail fiber (a trimer of the tail protein gpI) protruding from the end of the lambda tail. The central tail fiber of λ binds to a host maltose transport protein (called LamB or MalB) in the outer membrane of the host. Binding of phage λ to its receptor under suitable conditions acts as a signal that triggers the injection of the phage DNA genome into the host to initiate replication.

The structure and functions of many parts of the contractile tails of Myoviridae have been revealed in depth, especially for the phage T4 tail. After the T4 long tail fibers attach to the host, the short tail fibers unfold from the baseplate and bind to a second receptor on the host surface. The baseplate remains attached to the cell and undergoes a dramatic reorganization in which it changes from a hexagon to a star shape, causing the sheath to contract and drive the internal tail tube into the cell. As the

iron-containing nail-shaped tip of the inner tail tube passes through the outer membrane, tail lysozyme molecules are released to create a small hole in the cell wall peptidoglycan layer. These combined actions allow the tip of the tail tube to reach the inner membrane, where a channel is created that allows the dsDNA genome to enter the cell and initiate replication.

Temperate Versus Virulent Bacteriophages

Virulent bacteriophages, once they have infected a host, are committed to go through their entire growth cycle including replication of the bacteriophage chromosome, production of progeny viral particles and the lysis of the host cell. Temperate phages, on the other hand, are able to grow lytically like their virulent counterparts, but they are also capable of going into a dormant state within the host. This dormant state is called lysogeny, and often involves integration of the phage chromosome into the host chromosome, as occurs with phage λ , or conversion of the phage chromosome into an autonomously replicating plasmid, as occur with phage P1. The seemingly normal host containing a dormant phage chromosome is called a lysogen. The dormant phage chromosome is maintained in a mostly silent state, until some change in the condition of the host (often related to stress, such as damage to the host DNA) acts as a signal to induce the phage to begin a lytic growth cycle, all the way through progeny release. The temperate phage in the lysogenic state makes a repressor protein which can repress nearly all phage functions, except for the synthesis of the repressor itself. If the repressor is subsequently destroyed, as it may be after DNA damage occurs within the cell, the phage initiates a normal lytic growth cycle, usually excising the phage chromosome from the host chromosome as an early step. How a temperate phage decides between a virulent and lysogenic mode of infection is a complex process that appears to depend on the conditions within the host cell at the time of infection. In a simplified version of the process, it is a balance between the production of sufficient repressor protein to shut down phage development and the antagonistic action of other factors that prevent repressor synthesis and function.

Injection

DNA Injection

As described above, all *Caudovirales* bacteriophage particles have tails with highly specialized parts with specific roles to mediate attachment and infection. The fundamental goal of attachment is the introduction of the viral DNA into the host to begin production of progeny virions. The detailed mechanism of DNA entry varies widely, from phage to phage. Although this process is called DNA injection, the phage particles do not act like syringes, as the name implies. In some cases it appears that chromosome entry is largely passive, a result of the DNA being very densely packed into the virion at a high concentration. The high concentration of DNA packaged in the phage capsid appears to play a role in the passive transfer of DNA out of the capsid into the host; this appears to be true for many phages, including phage T4 and phage λ . Other *Caudovirales*, such as phage T7 (family *Podoviridae*) and phage T5 (family *Siphoviridae*) have more elaborate programs of DNA injection with an initial stage that appears to be largely passive, followed by pause after only a fraction of the chromosome has been injected. Such paused DNA injection resumes only after proteins (encoded by the genes injected in the initial stage) act to restart chromosome entry or to actively pull the rest of the chromosome into the host in a controlled manner.

Protein Injection

Many *Caudovirales* inject both DNA and proteins into their hosts. The function of a few of these injected proteins is known, but in many cases remains mysterious. For example, phage T4 injects multiple copies of several proteins into the host. These include one protein that modifies the host RNA-polymerase, another that inhibits a host nuclease that targets and digests T4's highly modified DNA, and other proteins of unknown function. Surprisingly, most of phage T4's injected proteins are not absolutely required for infection and mutants that lack them are able to grow on many ordinary laboratory hosts. Phage N4 injects a very large and essential RNA polymerase protein that transcribes this phage's early genes. Phage T7 was thought to inject several large proteins into its host, but these have now been shown to be extruded from the capsid interior and subsequently form a structure which is the channel for the passage of DNA and other proteins into the host.

Host Interactions and Regulation of Gene Expression

Classes of Genes

A regulated program of gene expression begins soon after any *Caudovirales* has injected its DNA. The expression of phage genes can be divided by function, such as host takeover, replication, virion assembly, or lysis, but more often they are sorted by their temporal order of expression. In most cases gene expression is divided into early genes and late genes, although for some phage there may be a cascade of gene expression modes that occur sequentially. In a cascading series, early phage gene products control the expression of a set middle gene products, which control the expression of late genes.

Early Genes

Phage early genes are usually transcribed by the normal host RNA polymerase, while the expression of late genes is dependant on the expression of the early genes. The earliest genes expressed might include ones that produce proteins to counteract the host's anti-bacteriophage defensive systems, as occurs in phage T7. Early genes of temperate phages are those required to make the decision to become dormant or to grow normally and carry out the first steps of these processes, including, for example, the repressor gene and integration genes, or DNA replication and recombination genes. Early genes of virulent bacteriophages, such as phage T4, include genes for genome replication and genes that shut down unneeded host functions, such as host transcription and host protein synthesis, and may include other genes required to recycle host resources, for example, by specifically degrading the host chromosome to intermediates that can be re-used during the replication of the phage genome.

Late Genes

The proteins encoded by the late genes include the structural proteins required for the assembly of the bacteriophage virion, as well as those needed for packaging the genome into the virion and for cell lysis. Late gene expression is often dependant on early (or middle) gene expression because the late genes have transcriptional promoters that are not recognized by the normal host polymerase. The early genes may direct the synthesis of transcription factors that either (a) change the specificity of the host RNA polymerase or (b) modify the polymerase in other ways, in order to express the whole set of late genes at the appropriate time with high efficiency. Alternatively, one of the early genes may encode for an entirely new RNA polymerase with a new specificity that recognizes late gene promoters. Expression of the structural proteins to high levels allows the production of a large number of progeny phages.

Virion Assembly

Assembly Pathways

The assembly of *Caudovirales* virions is a highly ordered process in which separate subassemblies of the virion are built and then joined to form the mature virion. The assembly of capsids, tails and tail fibers each follows an independent assembly pathway in which individual protein components are added, usually sequentially, to a growing structure until it is complete.

Tail Assembly

The major components of a *Caudovirales* tail are a baseplate or tail tip, major tail proteins (one for a non-contractile tail; two for contractile tails, an inner tube protein and outer sheath protein), and termination or capping proteins to stabilize the completed tail and connect it to the head. Tail assembly begins with the formation of an initiator complex, which may be either a complete tail tip or a complete baseplate, that is assembled via a separate pathway. The initiator complex includes a template that specifies the length of the tail, the tape measure protein complex in a compact form and bound by tape measure-specific chaperone proteins. The major tail proteins bind to the initiator complex and assemble into a tube around the tape measure protein until the full length of the tape measure protein is enclosed and the termination proteins can bind and stabilize the tail.

Capsid Assembly
